EDITORS BIOGRAPHY

Michael J Goss, PhD, MSc, BSc, is a professor emeritus in the School of Environmental Sciences at the University of Guelph. Before taking on the joint editor-in-chief responsibilities with Margaret Oliver, he held a similar position for *Soil Use and Management*, a journal of the British Society of Soil Science of which he is an honorary fellow. He was an inaugural member of the European Society for Agronomy. Michael started his career at the Letcombe Laboratory before moving to Rothamsted Experimental Station and the Macaulay Land Use Research Institute (now the James Hutton Research Institute). In 1990 he was appointed to the Research Chair in Land Stewardship at the University of Guelph and in 2005 became the director of its Regional Campus near Ottawa.

Michael's research has covered soil plant relations, soil management, and agriculture's footprint on the environment. His focus has been on the physical properties of soil and their impacts on root growth, which he showed to be influenced by the role of the root cap. He broadened his approach to include the effects of tillage and land drainage on root exploration. This work stimulated his interest in the transport of materials, such as plant nutrients, pathogenic microbes, antibiotics, and biologically active compounds through the soil and their contamination of water resources. Michael's knowledge in this field resulted in his involvement in the public inquiry into the death of seven people, including children, from a microbially contaminated drinking water supply. He contributed, both to the investigation into how the contamination occurred and if any fault could be attributed to local agricultural practices, and to how to prevent future events.

Michael also developed an interest in the interrelationships between soil microbes and root systems, particularly the tripartite symbiosis between roots of legumes, mycorrhizal fungi, and rhizobia. He has been an energetic member of collaborative research programs in France and Germany, and in Portugal, where he continues his interest in the role of mycorrhiza in sustainable land management.

Michael has authored more than 180 publications including two books, one in its 2nd edition, and edited two others.

Margaret Ann Oliver (BSc, PhD)

Margaret's interest in soil began in her penultimate year at school when learning about different types of soil and their formation. She chose the University of Bristol, United Kingdom for her first degree because the geography course offered soil science and she was also able to do a degree in geology alongside. Her love for both subjects remains undiminished. She did her PhD in soil spatial analysis at the University of Birmingham. Her early research focused on the multivariate and geostatistical analysis of soil data, which she continued to use in various research projects. Her research interests expanded to include the application of a wide range of numerical and geostatistical methods to soil and other data including pollen counts, forestry, radon emission, remotely sensed imagery, precision agriculture, and the incidence of childhood cancer. Her specific interests have been in sample design for spatial analysis and eventual mapping, risk analysis associated with prescribed thresholds in relation to soil pollutants or deficiencies of crop nutrients, and the relations between different scales of spatial variation. Her most

recent research was in the field of precision agriculture. At both the Universities of Birmingham and Reading, she taught topics in soil science, statistical methods, and spatial analysis. At Reading she had a research group working on various projects such as imagery, sampling and mapping, precision agriculture, and human health.

She has published more than 100 academic papers and has made several contributions to books. She is the co-author of three books: *Statistical Methods in Soil and Land Resource Survey*, Oxford University Press (Webster, R and Oliver, M. A. 1990); *Geostatistics for Environmental Scientists*, Second Edition, John Wiley & Sons (Webster, R and Oliver, M. A. 2007), and *How to do the Basic Steps in Geostatistics: The Variogram and Kriging*, Springer, Dordrecht (Oliver, M.A. & Webster, R.2015). She has edited two books: *Geostatistical Applications for Precision Agriculture* (Springer, Dordrecht, 2010) and *Precision Agriculture for Sustainability and Environmental Protection* (Earthscan from Routledge, 2013).

Margaret retired officially from Reading in 2004, but as yet has not managed to escape from academia. She has retained a link and a base at the University as a visiting professor since January 2005. After retirement, she developed and taught geostatistics courses to outside groups for several years. She then started on the long path of editorial work, as an associate editor of the *European Journal of Soil Science* and eventually the editor-in-chief, assistant editor of *Mathematical Geosciences*, co-editor of *Precision Agriculture* with John Stafford, and finally the editor-in-chief of the *Encyclopedia of Soils in the Environment* with Michael Goss.

Margaret was made an honorary member of the British Society of Soil Science in 2021 to reflect her commitment to soil science through fellow research, teaching, and editorial work. She was honored by the Pedometrics Commission of the International Union of Soil Science by having an award named after her in 2015. It is the Margaret Oliver award for young pedometricians.

FOREWORD

Soil is the porous “skin” on the surface of the Earth that has formed over thousands of years of weathering, comprising minerals, organisms (both dead and alive), water, and air. Soil is more than just the sum of its parts. It serves several crucial ecological functions, from food and fiber production to water storage and purification to waste decomposition.

Increasingly we understand that everything is connected, and that soil is a “Critical Zone” that intersects with the hydrosphere (water), lithosphere (minerals), atmosphere (air), and biosphere (all living organisms). To quote Daniel Hillel, the 2012 World Food Prize laureate and editor of the First Edition of *The Encyclopedia of Soils in the Environment*, “[Soil] is the crucible of terrestrial life, within which biological productivity is generated and sustained... Our civilization depends on the soil...” He also promoted the importance of understanding soil to manage it effectively. This revised and reorganized second edition of the Encyclopedia aims to reflect the changing status of soil in the world. Within these five volumes, over 724 experts from many countries have provided updated, easy-to-understand chapters on soil, its properties, and its role in the environment to affect climate change, plant productivity, human health, and biodiversity.

Many technological advances have been made since the first edition of this encyclopedia that has allowed us to investigate soil physical, chemical, and especially biological properties more precisely, enabling us to identify and understand their roles in ecosystem services. The study of soils, especially in the environmental context, is critical to meeting the challenges of feeding, clothing, and cleaning up the world. The information presented in these volumes will be useful to many, including soil and environmental scientists, policymakers, land managers, educators, students, and anyone interested in learning more about soil.

Soil is under considerable threat from many sources—building and infrastructure, climate change, population pressure, and pollution, yet it is vital to agronomic productivity and continues to provide critical ecosystem services. Society needs to be engaged in how soil is managed and conserved. Most natural scientists are very dedicated and generous, including all of the authors in this Encyclopedia who have freely given their time to make these volumes so comprehensive. The study of soil, while often challenging, is fascinating—soil is a beautiful earthy material that can delight our senses with its variegated colors, gritty to smooth textures, and especially its characteristic aroma when freshly turned. Perhaps that is why gardeners and even some farmers tend to overwork their soil to its detriment—it *just feels good to get your hands in the dirt!*

Soil science is one of the most exciting, interesting, and rewarding disciplines, largely because it is multi-dimensional and interdisciplinary, basic and applied. It affects all of our lives. Thus, I encourage you to peruse these volumes and discover all kinds of interesting aspects of soil in the environment.

April Ulery

Former President, Soil Science Society of America
Professor, Soil & Environmental Sciences
New Mexico State University
Las Cruces, NM
The United States

PREFACE

This second edition of the *Encyclopedia of Soils in the Environment* follows in the footsteps of a highly rated first edition overseen by Professor Daniel Hillel as editor in chief, ably assisted by six editors. That edition provided a very valuable resource on the “state-of-the-art” in soil science in the context of the environment in the closing years of the twentieth century and the first three years of the current century. It set a standard that the editorial team for the second edition has aimed to match. The soil and environmental sciences have made huge strides in the almost 20 years since the first edition was published, and the new team has had to embrace these developments while retaining the basic components of these sciences. The project has taken 4 years to complete. It began with the appointment of the two editors-in-chief, professors Michael J. Goss and Margaret A. Oliver, followed by that of the nine subject editors and a pedology adviser.

The project was in its infancy (a few months only) when COVID-19 struck. The editors-in-chief discussed the format and structure of the second edition around the time that the first “lockdowns” around the world were being introduced. The first edition was alphabetically organized, whereas we decided to have a section-oriented approach in this edition, which we hope gives a more structured feel for the various topics embraced. The principal sections are soil biology, soil chemistry, the soil environment and its management, pedology (the origins and development of soil), pedometrics (the application of mathematics and statistics to soil), and soil physics. We were able to give our full attention to this development and to the selection of the scientists to join us on the road ahead. Furthermore, we were fortunate to choose a team that has maintained its enthusiasm despite the many tribulations we have faced along this path. The team comprises Jane Blagodatskaya and Adrian Unc (biology and microbiology), Siobhan Staunton and Baoshan Xing (chemistry), Karin Müller and Christina Siebe (environment and management), Rupert Bäumler (pedology), Uta Stockmann and Margaret Oliver (pedometrics), and Paul Hallett and Dani Or (physics). The editorial board has been mindful in their choice of subjects of the need for basic soil science and for state-of-the-art developments, with the aim that the audience for these volumes can be as large as possible.

During the gestation period of the Encyclopedia, methods of working for those in academia were turned on their heads. The change from “face-to-face” teaching to formulating and establishing online courses, initially for lockdown periods but then for much of the next 2 years, had huge consequences for academic staff worldwide. This meant that they had less time to devote to outside activities, such as writing chapters for an encyclopedia. As a result, some authors were unable to complete their chapters in time, leaving a few unfortunate gaps. The whole team has done as much as they can to limit any adverse effects, but we ask readers to appreciate the struggle that authors have had with illness (personal, within their families and work colleagues) and a great increase in their workload. Despite this, we are presenting a comprehensive document that should stand the test of the next 20 years of soils in the environment.

This century has seen an almost unprecedented interest in the soil and environmental sciences. It has been triggered not only by issues that the Earth is facing from global climate change, increasing population pressure, soil and land degradation, and food insecurity but also by the many new and sophisticated methods available, such as the DNA determination of microbial populations and their functional capabilities, proximal sensing, machine learning methods, and an ever-increasing array of technological tools. These developments have greatly increased our knowledge and appreciation of the complexity of soils, which has changed our understanding of some well-established aspects of the science. The soil and its environment are at the critical interface of the atmosphere, biosphere, hydrosphere, and lithosphere. They deserve to be taken seriously by the international community in the same way that air and water have been. Governments are now paying attention

to the soil and environment, and a legal and governance framework is emerging to look after these parts of our life support resources.

We have aimed, through our editing of chapters, to make the language of the chapters accessible to all, regardless of educational background. This does not mean that we have diminished the scientific content, but that readers should be able to gain the foothold they desire in these subjects to progress to greater knowledge and understanding of them. We have retained the overview of soil written by Daniel Hillel for the First Edition, first to honor his great contribution to soil science and second to demonstrate the significance of soil. It follows this Preface.

*Michael J. Goss
Margaret A. Oliver*

SOIL

The term “soil” refers to the weathered and fragmented outer layer of our planet’s land surfaces. Formed initially through the physical disintegration and chemical alteration of rocks and minerals by physical and biogeochemical processes, soil is influenced by the activity and accumulated residues of a myriad of diverse forms of life. As it occurs in different geologic and climatic domains, soil is an exceedingly varied body with a wide range of attributes.

Considering the height of the atmosphere, the thickness of the earth’s rock mantle, and the depth of the ocean, one observes that soil is an amazingly thin body—typically not much more than one meter thick and often less than that. Yet it is the fount of terrestrial life, within which biological productivity is generated and sustained. It acts like a composite living entity, a home to a community of innumerable microscopic and macroscopic plants and animals. A mere fistful of soil typically contains billions of microorganisms, which perform vital interactive biochemical functions. Another intrinsic attribute of the soil is its sponge-like porosity and its enormous internal surface area. That same fistful of soil may actually consist of several hectares of active surface, upon which physicochemical processes take place continuously.

Realizing humanity’s utter dependence on the soil, ancient peoples, who lived in greater closeness to nature than many of us today, actually revered the soil. It was not only their source of livelihood but also the material from which they built their homes and that they learned to shape, heat, and fuse into household vessels and writing tablets (ceramics, made of clayey soil, being the first synthetic material in the history of technology). In the Bible, the name assigned to the first human was Adam, derived from “adama,” meaning soil. The name given to the first earthling’s mate was Hava (Eve, in transliteration), meaning “living” or “life-giving.” Together, therefore, Adam and Eve signified quite literally “Soil and Life.”

The same powerful metaphor is echoed in the Latin name for human species—Homo, derived from humus, the material of the soil. Hence, the adjective “human” also implies “of the soil.” Other ancient cultures evoked equally powerful associations. To the Greeks, the earth was a manifestation of Gaea, the maternal goddess who, impregnated by Uranus (god of the sky), gave birth to all the gods of the Greek pantheon.

Our civilization depends on the soil more crucially than ever because our numbers have grown while available soil resources have diminished and deteriorated. Paradoxically, however, even as our dependence on the soil has increased, most of us have become physically and emotionally detached from it. Many of the people in the so-called developed countries spend their lives in the artificial environment of a city, insulated from direct exposure to nature, and some children may now assume as a matter of course that food originates in supermarkets.

Detachment has bred ignorance, and out of ignorance has come the delusion that our civilization has risen above nature and has set itself free of its constraints. Agriculture and food security, erosion and salination, degradation of natural ecosystems, depletion and pollution of surface waters and aquifers, and decimation of biodiversity—all these processes, which involve the soil directly or indirectly, have become abstractions to many people. The very language we use betrays disdain for that common material underfoot, often referred to as “dirt.” Some fastidious parents prohibit their children from playing in the mud and hurry to wash their “soiled” hands when the children nonetheless obey an innate instinct to do so. Thus, soil is devalued and treated as unclean though it is the terrestrial realm’s principal medium of purification, wherein wastes are decomposed and nature’s productivity is continually rejuvenated.

Scientists who observe soil closely see it in effect as a seething foundry in which matter and energy are in constant flux. Radiant energy from the sun streams onto the field and cascades through the soil and the plants growing in it. Heat is exchanged, water percolates through the soil’s intricate passages, and plant roots extract

water and transmit it to their leaves, which transpire it back to the atmosphere. Leaves absorb carbon dioxide from the air and synthesize it with soil-derived water to form the primary compounds of life. Oxygen emitted by the leaves makes the air breathable for animals, which consume and in turn fertilize plants.

Soil is thus a self-regulating bio-physio-chemical factory, processing its own materials, water, and solar energy. It also determines the fate of rainfall and snowfall reaching the ground surface—whether the water thus received will flow over the land as runoff, or seep downward to the subterranean reservoir called groundwater, which in turn maintains the steady flow of springs and streams. With its finite capacity to absorb and store moisture, and to release it gradually, the soil regulates all these phenomena. Without the soil as a buffer, rain falling over the continents would run off entirely, producing violent floods rather than sustained river flow.

Soil naturally acts as a living filter, in which pathogens and toxins that might otherwise accumulate to foul the terrestrial environment are rendered harmless. Since time immemorial, humans and other animals have been dying of all manner of diseases and have then been buried in the soil, yet no major human disease is transmitted by it. The term antibiotic was coined by soil microbiologists who, as a consequence of their studies of soil bacteria, specifically actinomycetes, discovered streptomycin (an important cure for tuberculosis and other infections). Ion exchange, a useful process of water purification, also was discovered by soil scientists studying the passage of solutes through beds of clay.

However unique in form and function, soil is not an isolated body. It is, rather, a central link in the larger chain of interconnected domains and processes comprising the terrestrial environment. The soil interacts both with the overlying atmosphere and the underlying strata, as well as with surface and underground bodies of water. Especially important is the interrelation between the soil and climate. In addition to its function of regulating the cycle of water, it also regulates energy exchange and surface temperature.

When land is cleared of vegetation and turned into a cultivated field, the native biomass above the ground is often burned and the organic matter within the soil tends to decompose. These processes release carbon dioxide into the atmosphere, thus contributing to the Earth's greenhouse effect and to global warming. On the other hand, the opposite act of afforestation and soil enrichment with organic matter, such as can be achieved through conservation management, may serve to absorb carbon dioxide from the atmosphere. To an extent, the soil's capacity to store carbon thus helps to mitigate the greenhouse effect.

Thousands of years are required for nature to create life-giving soil out of sterile bedrock. In only a few decades, however, unknowing or uncaring humans can destroy that wondrous work of nature. In various circumstances, mismanaged soils may be subject to erosion (the sediments of which tend to clog streambeds, estuaries, lakes, and coastal waters), to leaching of nutrients with attendant loss of fertility and eutrophication of water bodies, to waterlogging and impaired aeration, or to an excessive accumulation of salts that may cause a once-productive soil to become entirely sterile. Such processes of soil degradation, sometimes called "desertification," already affect large areas of land.

We cannot manage effectively and sustainably that which we do not know and thoroughly understand. That is why the tasks of developing and disseminating sound knowledge of the soil and its complex processes have assumed growing urgency and importance. The global environmental crisis has created a compelling need for a concentrated, concise, and definitive source of information—accessible to students, scientists, practitioners, and the general public—about the soil in all its manifestations in nature and in relation to the life of humans.

Daniel Hillel

*Departamento de Ciencias Biológicas, Facultad de Ciencias
de la Salud, Universidad Técnica de Manabí, Portoviejo,
Ecuador*

Chandra A Madramootoo

*Department of Bioresource Engineering, Macdonald
Campus of McGill University, Ste-Anne-de-Bellevue, QC,
Canada*

Tolulope Mafa-Attoye

*School of Environmental Sciences, University of Guelph,
Guelph, ON, Canada*

Ali Akbar Mahboubi

Department of Soil Science, College of Agriculture, Bu-Ali Sina University, Hamadan, Iran; School of Engineering, University of Guelph, Guelph, Ontario, Canada

Evan Mayer

School of Environmental Sciences, University of Guelph, Guelph, ON, Canada

Mallavarapu Megharaj

Global Centre for Environmental Remediation (GCER), and Cooperative Research Centre for Contamination Assessment and Remediation of the Environment (CRC CARE), College of Engineering, Science and Environment, The University of Newcastle, Callaghan, NSW, Australia

Eduardo K Mitter

School of Environmental Sciences, University of Guelph, Guelph, ON, Canada

Mehrdad Mohammadiani

Department of Microbiology, University of Manitoba, Winnipeg, Canada

Mohammad Reza Mosaddeghi

Department of Soil Science, College of Agriculture, Isfahan University of Technology, Isfahan, Iran

Krisztina Mosdossy

Department of Natural Resource Sciences, Macdonald Campus of McGill University, Sainte-Anne-de-Bellevue, QC, Canada

Florence Mus

Institute of Biological Chemistry, Washington State University, Pullman, WA, United States

Deborah A Neher

Department of Plant and Soil Science, University of Vermont, Burlington, VT, United States

Jeanette M Norton

Department of Plants, Soils and Climate and Ecology Center, Utah State University, Logan, UT, United States

Dasiel Obregon

School of Environmental Sciences, University of Guelph, Guelph, ON, Canada

Maureen O'Callaghan

Resilient Agriculture, AgResearch, Christchurch, New Zealand

Yang Ouyang

Department of Microbiology and Plant Biology, Institute of Environmental Genomics, University of Oklahoma, Norman, OK, United States

NS Panikov

Chemistry and Chemical Biology Department, Northeastern University, Boston, MA, United States

Carlos B Pires

Kansas State University, Manhattan, KS, United States

Thomas O Powers

Department of Plant Pathology, University of Nebraska, Lincoln, NE, United States

Balasubramanian Ramakrishnan

Division of Microbiology, ICAR-Indian Agricultural Research Institute, New Delhi, India

K Ramesh Reddy

University of Florida, Soil and Water Sciences Department, Wetland Biogeochemistry Laboratory, Gainesville, FL, United States

Natasha Rayne

University of Wisconsin River Falls, River Falls, WI, United States

Marc Redmile-Gordon

Department of Environmental Horticulture, Royal Horticultural Society, Wisley, United Kingdom

Charles W Rice

Kansas State University, Manhattan, KS, United States

Andreas Richter

Centre for Microbiology and Environmental Systems Science, University of Vienna, Vienna, Austria; International Institute for Applied Systems Analysis, Advancing Systems Analysis Program, Laxenburg, Austria

Sarah S Roley

School of the Environment, Washington State University, Richland, WA, United States

Azadeh Safadoust

Department of Soil Science, College of Agriculture, Bu-Ali Sina University, Hamadan, Iran

D Said-Pullicino

University of Torino, Department of Agricultural, Forest and Food Sciences, Torino, Italy

Gustavo Santoyo

Instituto de Investigaciones Químico Biológicas, Universidad Michoacana de San Nicolás de Hidalgo, Morelia, Mexico

Marcos VM Sarto

Kansas State University, Manhattan, KS, United States

Mikhail V Semenov

Dokuchaev Soil Science Institute, Laboratory of Soil Carbon and Microbial Ecology, Moscow, Russian Federation

Balwant Singh

Sydney Institute of Agriculture, School of Life and Environmental Sciences, The University of Sydney, Sydney, NSW, Australia

Heather Slinn
*School of Environmental Sciences, University of Guelph,
Guelph, ON, Canada*

Donald L Sparks
*Department of Plant and Soil Sciences, University of
Delaware, Newark, DE, United States*

Micaela Tosi
*School of Environmental Sciences, University of Guelph,
Guelph, ON, Canada*

AL Ulery
*Plant & Environmental Sciences Department, New Mexico
State University, Las Cruces, NM, United States*

Adrian Unc
*School of Science and the Environment, Memorial
University of Newfoundland, Corner Brook, NL, Canada*

Jeremiah D Vallotton
*Environmental Science Program, Memorial University of
Newfoundland, St. John's, NL, Canada*

Viacheslav Vasenev
*Soil Geography and Landscape Group, Wageningen
University, Wageningen, The Netherlands*

Maria Vasilieva
*Agrarian-Technological Institute, RUDN University,
Moscow, Russia*

Kadiyala Venkateswarlu
*Formerly Department of Microbiology, Sri Krishnadevaraya
University, Anantapuramu, India*

Diana H Wall
*School of Global Environmental Sustainability, Colorado
State University, Fort Collins, CO, United States*

Chaoqun Wang
*Biogeochemistry of Agroecosystems, University of
Goettingen, Goettingen, Germany*

Joann K Whalen
*Department of Natural Resource Sciences, Macdonald
Campus of McGill University, Sainte-Anne-
de-Bellevue, QC, Canada; Chair of Soil Science,
Mohammed VI Polytechnic University, Ben Guerir,
Morocco*

David Wright
*Resilient Agriculture, AgResearch, Christchurch, New
Zealand*

Hsin-Hua Wu
*Institute of Biological Chemistry, Washington State
University, Pullman, WA, United States; Department of
Chemistry, Washington State University, Pullman, WA,
United States*

Yichao Wu
*State Key Laboratory of Agricultural Microbiology, College
of Resources and Environment, Huazhong Agricultural
University, Wuhan, China*

Sabina Yeasmin
*Department of Agronomy, Bangladesh Agricultural
University, Mymensingh, Bangladesh*

Dan-Ting Yu
*State Key Laboratory for Subtropical Mountain
Ecology of the Ministry of Science and Technology
and Fujian Province, Fujian Normal University, Fujian,
China*

CONTENTS OF ALL VOLUMES

VOLUME 1: SOIL BIOLOGY

Overview

Edaphology	1
<i>RM Goss and AL Ulery</i>	

Biodiversity	10
<i>Monica A Farfan and Diana H Wall</i>	

Soil organisms

Bacteriophage (Viruses)	16
<i>Li Bi, Ji-Zheng He, Dan-Ting Yu, Li-Li Han, and Hang-Wei Hu</i>	

Archaea	25
<i>Mikhail V Semenov</i>	

Bacteria	31
<i>Mikhail V Semenov</i>	

Soil protists	39
<i>Stefan Geisen, Nathalie Amacker, and Alexandre Jousset</i>	

Fungi including mycorrhizal fungi	49
<i>F Buscot</i>	

Soil algae	61
<i>Karen Baumann and Patrick Jung</i>	

Soil arthropods: Underfoot and all around	70
<i>Ernest C Bernard</i>	

Nematodes	105
<i>Deborah A Neher and Thomas O Powers</i>	

Earthworms: Essential ecosystem engineers providing vital ecosystem services	112
<i>Maria JI Briones</i>	

Complex structures

Soil biofilms: Evolving concepts and ecological functions	120
<i>Yichao Wu, Marc Redmile-Gordon, Peng Cai, Chunhui Gao, and Qiaoyun Huang</i>	

Biocrusts	127
<i>Matthew A Bowker, Jasmine Anenberg, Hilina Yohannes Kebede, Anita Antoninka, and Lydia Bailey</i>	

Functioning

Studying soil microbial communities: Culture-dependent approaches	139
<i>Eduardo K Mitter, Dasiel Obregon, Micaela Tosi, Heather Slinn, and Kari Dunfield</i>	

Studying soil microbial communities: Culture-independent approaches	146
<i>Tolulope Mafa-Attoye, Heather Slinn, Micaela Tosi, Evan Mayer, Dasiel Obregon, and Kari Dunfield</i>	

Studying microbial function in soil: Culture-independent techniques <i>Micaela Tosi, Dasiel Obregon, Heather Slinn, and Kari Dunfield</i>	155
Kinetics of microbial processes: General principles <i>NS Panikov</i>	168
Kinetics of microbial processes: Applications to soil biology <i>NS Panikov</i>	186
Biogeochemical cycles	
Carbon cycle in soils: Dynamics and management <i>Charles W Rice, Carlos B Pires, and Marcos VM Sarto</i>	219
Carbon storage in soils <i>Isabelle Basile-Doelsch, Tiphaine Chevallier, Marie-France Dignac, and Amandine Erktan</i>	228
Soil organic nitrogen <i>EJ Daly and KA Congreves</i>	243
Nitrification: Process, organisms and management <i>Jeanette M Norton and Yang Ouyang</i>	253
Microbial denitrification <i>Michael J Goss, Sergey Blagodatsky, and Adrian Unc</i>	261
Symbiotic nitrogen fixation <i>Florence Mus and Hsin-Hua Wu</i>	270
Nitrogen: Non-Symbiotic Nitrogen fixation in soils <i>Vadakattu VSR Gupta and Sarah S Roley</i>	283
Phosphorus in soils—Biological interactions <i>Nataliya Bilyera and Iryna Loginova</i>	293
Biological transformations of sulfur in soil <i>Chaoqun Wang and Maxim Dorodnikov</i>	303
Plant uptake of mineral nutrients <i>Angela Hodge</i>	310
Higher plants and their interactions with soil organisms	
Soil Biology: Root form and function <i>Magda Garbowski, Grégoire Freschet, Louise Jackson, Cynthia Brown, and Louise Comas</i>	321
Root mucilage: Chemistry and functions in soil <i>Yutong Jiang, Lijun Hou, Fang Ding, and Joann K Whalen</i>	332
Root exudates and microorganisms <i>Aidan De Sena, Krisztina Mosdossy, Joann K Whalen, and Chandra A Madramootoo</i>	343
Root interactions with the microbiome from the rhizoplane to the bulk soil: An overview <i>Joann K Whalen and Shamim Gul</i>	357
Microorganisms & biological processes	
Soil respiration <i>Jeremiah D Vallotton, Sergey Blagodatsky, and Adrian Unc</i>	369
Anaerobic soil processes <i>PW Inglett, D Said-Pullicino, and K Ramesh Reddy</i>	379
Mineral-organic-microbial interactions <i>Balwant Singh, Sabina Yeasmin, and Donald L Sparks</i>	387

Microbial ecology & management

Habitat for soil organisms and their functions <i>Alexandra Kravchenko and Andrey Guber</i>	407
Plant growth promoters <i>Elisa Gamalero, Gustavo Santoyo, and Bernard R Glick</i>	418
Inoculation with microorganisms <i>Maureen O'Callaghan and David Wright</i>	428
Biocontrol of soil-borne plant diseases <i>Mehrdad Mohammadiani and Matthew Bakker</i>	439
Management of soil biology for crop protection from biotic and abiotic stresses <i>Michael J Goss, Isabel Brito, and Mário Carvalho</i>	447
Trees, hedges, agroforestry and microbial diversity <i>Josiah B Judson, Joseph Holden, Pippa Chapman, and Marcelo Valadares Galdos</i>	469
Urban soil microbiome: Activity, diversity and functioning <i>Maria Korneykova, Ekaterina Kozlova, Kristina Ivashchenko, Maria Vasilieva, and Viacheslav Vasenev</i>	480
Microbiology of extreme soil environments <i>Patrice Dion</i>	494
Microbial mobility and transport in soils <i>Mohammad Reza Mosaddeghi, Adrian Unc, Ali Akbar Mahboubi, and Azadeh Safadoust</i>	512

Biology of soil amendments & contaminant degradation

Biology of compost <i>Heribert Insam, Thomas Klammersteiner, and María Gómez-Brandón</i>	522
Landfarming and its microbiology <i>Naga Raju Maddela, Balasubramanian Ramakrishnan, Kadiyala Venkateswarlu, and Mallavarapu Megharaj</i>	533
Biodegradation of organic contaminants <i>PB Hatzinger and JW Kelsey</i>	547
Biological aspects of manure management <i>Natasha Rayne and Bee Khim Chim</i>	558
Septic systems and municipal waste disposal on land <i>Charles P Gerba, Michael J Goss, and Adrian Unc</i>	567

Climate change

Climate change impacts on soil biology <i>Alberto Canarini, Lucia Fuchslueger, François-Xavier Joly, and Andreas Richter</i>	578
---	-----

VOLUME 2: CHEMISTRY**Basic Soil Chemistry**

Acidity and acidification <i>Siobhan Staunton</i>	1
pH <i>Siobhan Staunton</i>	8
Buffering capacity <i>Siobhan Staunton and Ravi Naidu</i>	15
Soil specific surface area <i>Emmanuel Arthur, Markus Tuller, and Kurt D Pennell</i>	22

Soil Analytical Chemistry

Cation exchange capacity and reactions <i>Donald S Ross and Ulf Skyllberg</i>	32
Testing for nutrients in the soil and the environment <i>Antonio P Mallarino</i>	43
Metal extraction and analysis <i>Guo Wang and Honghong Li</i>	50
Soil organic matter: Composition <i>Markus Kleber</i>	58
Physical fractionation techniques <i>Sam J Leuthold, Michelle L Haddix, Jocelyn Lavallee, and M Francesca Cotrufo</i>	68
The use of stable isotopes in soil science: Low atomic number elements <i>Chiara Pistocchi, Isabelle Bertrand, Kristýna Kantnerová, Astrid Oberson, Federica Tamburini, and Roland A Werner</i>	81
The use of radioactive isotopes to study soil pools and processes <i>Timothy I McLaren</i>	96
The use of stable isotopes in soil science: Metals <i>Cécile Quantin and Damien Guinoiseau</i>	107

Periodic Table

Alkali metals in soils <i>Guy J Levy and Asher Bar-Tal</i>	116
Alkaline earth metals in soil <i>Justin B Richardson</i>	126
Transition metals in soil <i>Siobhan Staunton</i>	135
Nitrogen and ammonia in soils <i>Nicholas T Girkin and Hannah V Cooper</i>	142
Phosphorus in soil <i>Luisella Celi, Maria Martin, and Elisabetta Barberis</i>	152
Aluminum in soils <i>Syuntaro Hiradate</i>	167
Iron in soils <i>Trolard Fabienne and Guilhem Bourrié</i>	176
Sulfur and selenium in soil <i>Dongli Liang, Fei Zhou, and Mingxing Qi</i>	192
Arsenic in soil <i>Md Imran Ullah Sarkar, Afsana Jahan, Md Tofail Hossain, Mohammad Mahmudur Rahman, and Ravi Naidu</i>	201
Non-transition elements: Metals and metalloids in soils <i>Natasha, Sana Khalid, Muhammad Shahid, Faiz Rabbani, and Camille Dumat</i>	214
Lanthanides, actinides and radon <i>Franco Ajmone Marsan and Mery Malandrino</i>	225
Halogens in soils <i>Svensson Teresia, Thiry Yves, Bueno Maïté, and Oelmann Yvonne</i>	234
Transformation of metals and metalloids by microorganisms <i>Susan M Glasauer, Euan P Burford, and Geoffrey Michael Gadd</i>	243
Dynamics of radionuclides <i>Siobhan Staunton</i>	256
Silicon and other non-metal elements from Group 14 <i>Bruno Delvaux and Zimin Li</i>	263

Soil Physical Chemistry

Chemical equilibria	274
<i>Arthur Paul Schwab</i>	
Dissolution and precipitation processes	284
<i>Zhenqing Shi, Shiwen Hu, Rong Li, and Yang Lu</i>	
Reactions, redox potential and kinetics	297
<i>Trolard Fabienne and Guilhem Bourrié</i>	
Sorption of organic chemicals in soil	315
<i>Joseph J Pignatello</i>	
Sorption—Oxyanions	327
<i>CP Schulthess, H Wijnga, W Yang, Anahita Khosravi, and Baoshan Xing</i>	
Sorption—Metals	336
<i>Daniel G Strawn and Donald L Sparks</i>	
Sorption-desorption kinetics	343
<i>Gautier Landrot and Donald L Sparks</i>	
Sorption-desorption hysteresis	355
<i>Wenhao Wu, Hongxia Zhu, and Kun Yang</i>	
Surface charge and zero-charge points	368
<i>J Chorover</i>	
Flocculation and dispersion	376
<i>Guy J Levy and Isaac Shainberg</i>	

Soil Carbon Chemistry

Soil organic matter dynamics	387
<i>Yu Luo and Jianming Xu</i>	
Soil proteins	396
<i>Siobhan Staunton</i>	
Biochar: Properties, mechanisms, and interactions in the soil	406
<i>Balwant Singh, Shamim Mia, and Marta Camps-Arbestain</i>	
Dissolved organic carbon	421
<i>Jason James and Rob Harrison</i>	
Black carbon, pyrogenic carbon	432
<i>Heike Knicker</i>	
Fire effects on soil	448
<i>Stefan H Doerr, Cristina Santín, and Jorge Mataix-Solera</i>	
Interfacial reactions of microorganisms with minerals and organic matter	458
<i>Rota Wagai, Puu-Tai Yang, and Klaus Kaiser</i>	
Pesticide fate in soils	470
<i>Pierre Benoit, Laure Mamy, Carole Bedos, and Enrique Barriuso</i>	
Soil organic matter in molecular simulations	483
<i>Martin H Gerzabek, Daniel Tunega, Edgar Galicia-Andrés, and Chris Oostenbrink</i>	

Soil Physical Analysis

Raman spectroscopy	497
<i>Anupam Das and Huiyuan Guo</i>	
Fourier transform infrared spectroscopic methods of soil analysis	510
<i>Derek Peak</i>	
Electron paramagnetic resonance spectroscopy: Part I Historical Perspectives	519
<i>Giorgio S Senesi and Nicola Senesi</i>	

Electron paramagnetic resonance spectroscopy: Part II the view forward <i>Robert L Cook, Emmanuel Ampiah, Phillip T Sprunger, and Randall W Hall</i>	533
Fluorescence Spectroscopy: Part I Principles <i>Yong Zhang, Shuai Guo, and Chaoxian Wei</i>	544
Fluorescence spectroscopy: Part II practical applications <i>Yong Zhang, Chaoxian Wei, and Shuai Guo</i>	552
Near and mid infrared soil spectroscopy <i>Wartini Ng, Brendan Malone, Budiman Minasny, and Sangho Jeon</i>	567
Electron microscopic methods (TEM, SEM and energy dispersal spectroscopy) <i>Jian Zhao and Xia Liu</i>	575
Application of atomic force microscopy (AFM) on environmental interfaces <i>Saikat Ghosh, Zhang Di, Bo Pan, and Baoshan Xing</i>	589
Applications of nuclear magnetic resonance for the study of soils <i>Daniel H Lysak, Myrna J Simpson, and Andre J Simpson</i>	605
Neutron-gamma analysis of soil elements <i>Aleksandr Kavetskiy, Galina Yakubova, Nikolay Sargsyan, Stephen A Prior, and H Allen Torbert</i>	625
X-Ray Diffraction <i>Chao Wang and Cheng Gu</i>	642
Soil analysis using laser-induced breakdown spectroscopy <i>Débora Marcondes Bastos Pereira Milori, Ladislau Martin-Neto, Hero T Gollany, Diego Victor de Babos, Luis Carlos Leva Borduchi, and Paulino Ribeiro Villas-Boas</i>	654
Calorimetric analysis <i>Xingmin Rong and Qiaoyun Huang</i>	662
Understanding of soil processes at the microscale—Use of NanoSIMS in soil science <i>Carsten W Mueller, Carmen Hoeschen, and Ingrid Koegel-Knabner</i>	670
Nanoparticles in soil <i>Di Lang, Quan Chen, Yang Liu, and Bo Pan</i>	681
Overview	
Soil chemistry and climate change <i>Jianming Xu, Yong Li, and Zhongmin Dai</i>	692
VOLUME 3: ENVIRONMENT AND MANAGEMENT	
Soil functions, potential uses of soil and ecosystem services	
Soil functions, soil potential uses and ecosystem services <i>Karl Stahr</i>	1
Farming systems to conserve land for nature <i>Rattan Lal</i>	12
Geoarchaeology and soils <i>Carlos E Cordova</i>	20
Civilizations and the role of soil, agriculture, and climate change <i>Jeffrey A Homburg, Eric C Brevik, and Jonathan A Sandor</i>	29
Ecosystem services provided by soils in highly anthropized areas (SUITMAs) <i>Jean Louis Morel, Geoffroy Séré, Viatcheslav Vasenev, and Thomas Nehls</i>	37
Structure and function of forested soils <i>Peter Clinton and Jen Owens</i>	56
Agroforestry <i>NV Thevathasan, AM Gordon, and PKR Nair</i>	68

Rangeland management <i>Alexandra Sandhage-Hofmann</i>	88
Effects on soil of grassland management for pasture, hay and silage <i>Carmen Segura, Laura Cardenas, Richard McDowell, Sarah Morgan, and Martin SA Blackwell</i>	102
Dryland farming: Technological and management options for sustainable agriculture and food systems <i>Ch Srinivasarao, G Ranjith Kumar, Ravula Manasa, Kiran Pilli, Samaresh Sahoo, S Rakesh, Sumanta Kundu, K C Nataraj, KV Rao, JVNS Prasad, and S Malleswari</i>	113
The effect of crop rotations on soil <i>Caio Fernandes Zani, Arlete Simões Barneze, Rogério Peres Soratto, and Charles Andrew Francis</i>	125
The contribution of organic farming systems to soil fertility—A systems perspective <i>Bernhard Freyer, Pierre Ellssel, Jürgen K Friedel, and Kurt Möller</i>	135
Soil functions to support natural plant communities and crops: Soil multifunctionality <i>Leidivan Almeida Frazão, Luiz Arnaldo Fernandes, Adriana Marcela Silva Olaya, and Igor Costa de Freitas</i>	146
Methane and nitrous oxide emissions from land <i>Joanna M Cloy and Keith A Smith</i>	153
Soil and land degradation	
Overview chapter on soil degradation <i>K Müller, Margaret A Oliver, and C Siebe</i>	165
Soil monitoring <i>Ben Marchant and Nicolas Saby</i>	172
Soil quality and health key indicators <i>Edoardo AC Costantini and Simone Priori</i>	181
Water induced soil erosion <i>R Jane Rickson</i>	193
Erosion by wind <i>John Tatarko</i>	208
Human exposure to aeroparticles emitted from unpaved roads due to traffic resuspension and wind erosion <i>Arón Jazcilevich and Ann G Wellens</i>	223
Soil salination processes and management <i>Uri Nachshon and Guy J Levy</i>	236
Degradation of soil structure and soil organic matter <i>Andrew S Gregory</i>	246
Drainage, soil water storage, buffering and filtering <i>Jeffrey Strock and Norm Fausey</i>	257
Environmental effects of irrigation <i>Sevilay Topcu</i>	266
Trade-offs of wastewater irrigation <i>Manzoor Qadir and Christopher A Scott</i>	277
Pollution and risks of trace elements in the soil environment <i>Peng Wang, Fang-Jie Zhao, and Steve P McGrath</i>	288
Pollutants—Persistent organic <i>Rai S Kookana and Divina A Navarro</i>	296
Pollution by microplastic in agricultural areas <i>Nicolas Beriot and Esperanza Huerta-Lwanga</i>	309

Municipal solid waste management: Production, management, and environmental effects <i>Bryant M Serre and Lynda H McCarthy</i>	321
Remediation of metals and organic contaminants in soil <i>Peter Sanderson, Md Mezbaul Bahar, Bhabananda Biswas, and Ravi Naidu</i>	333
Soil change under different scenarios	
Soil change under different scenarios <i>Joann K Whalen</i>	344
The effect of global change on the soil body <i>Sophie Cornu, David Montagne, and Antra Boca</i>	360
The effects of adequate and excessive application of mineral fertilizers on the soil <i>Bijay-Singh and Tek B Sapkota</i>	369
Foliar Application of Nutrients <i>Thomas Eichert and Victoria Fernández</i>	382
Mulches and cover crops part I: Types <i>KK Bandyopadhyay, CL Acharya, and KM Hati</i>	392
Mulches and cover crops part II: Role in soil health and climate resilient agriculture <i>KK Bandyopadhyay, CL Acharya, and KM Hati</i>	401
The potential agronomic and environmental applications of biochar: Prospects and challenges <i>Yu-Jun Wang, Ping Wu, Nanthi S Bolan, and Hai-Long Wang</i>	414
Soil management for carbon sequestration <i>Christopher Brock, Uwe Franko, and Martin Wiesmeier</i>	424
Soil tillage <i>Mathieu Lamandé, Lars Juhl Munkholm, and Trond Børresen</i>	433
Weed and soil management: A balancing act <i>Trevor Kenneth James and Charles Norman Merfield</i>	439
Terraces as traditional agricultural landscapes. Stability amidst change <i>Gerardo Bocco</i>	450
Soil quality protection policies and plans to ensure sustainability <i>Ram Swaroop Meena and Sandeep Kumar</i>	457
Construction of Technosols for green roofs and vertical green system <i>Eleonora Flores-Ramírez, Stefan Abel, Elizabeth Chávez-García, and Geoffroy Séré</i>	473
Management of park areas, sport fields, and school yards, including golf courses and public right of ways <i>Maxine J Levin and Anna Paltseva</i>	488
Soil-society relations	
Overview chapter on soil-society relations <i>C Siebe, Margaret A Oliver, and K Müller</i>	505
Soil art: Sensory and symbolic engagement with soils <i>Alexandra R Toland and Daniel Wolter</i>	509
Soil science in the criminal justice system <i>Lorna Anne Dawson</i>	521
Soil governance at the international, regional and national level <i>Harald Ginzky</i>	532
The economics of soils' contribution to human well-being <i>Bartosz Bartkowski and Julian R Massenber</i>	547

Soil and human health	555
<i>Margaret A Oliver and Eric C Brevik</i>	
Soil Science Education, Awareness and Outreach in the Modern World	572
<i>Laura Bertha Reyes-Sánchez and Eric C Brevik</i>	
Soils in landscape planning	580
<i>Seth Denizen</i>	
VOLUME 4: PEDOLOGY	
Pedology	
Pedology—Basic principles	1
<i>Rupert Bäumler, Uta Stockmann, and Margaret A Oliver</i>	
Factors of soil formation, pedogenic processes and mineralogy	
Overview chapter on factors of soil formation	7
<i>Rupert Bäumler, Margaret A Oliver, and Uta Stockmann</i>	
Factors of soil formation: Climate	14
<i>Stefaan Dondeyne, Stephan Mantel, and Seppe Deckers</i>	
Factors of soil formation: Soil biota and organic matter as a factor for soil formation and weathering processes	25
<i>Scott Werts</i>	
Soil forming factors: Parent material	34
<i>Stephen Nortcliff</i>	
Parent materials: Loess	42
<i>Tobias Sprafke</i>	
Time	48
<i>Susan E Melzer, Caroline M Yonker, and Eugene F Kelly</i>	
Factors of soil formation—Human impacts	54
<i>Jonathan A Sandor, C Lee Burras, Michael Thompson, and Skye A Wills</i>	
Dynamic soils	69
<i>Markus Egli and Dennis Dahms</i>	
Interactions between soils and climate change	82
<i>Cornelia Rumpel</i>	
Primary minerals	91
<i>Balwant Singh</i>	
Mineral components of the soil clay fraction	109
<i>Darrell G Schulze</i>	
Short-range ordered aluminosilicates	121
<i>Tetsuhiro Watanabe, James B Harsh, and Rota Wagai</i>	
Metal oxides	135
<i>Andreas C Scheinost and Balwant Singh</i>	
Soil morphology	149
<i>Phillip R Owens and Zamir Libohova</i>	
Soil micromorphology	171
<i>Rosa M Poch and Georges Stoops</i>	
Soil Classification and distribution	
History and principles of soil classification	185
<i>Maria Gerasimova and Dmitry Konyushkov</i>	

Soil classification systems: World reference base and soil taxonomy	197
<i>David Badía-Villas</i>	
World reference base for soil resources (WRB)	206
<i>Stephan Mantel, Stefaan Dondeyne, and Seppe Deckers</i>	
World soil map based on soil taxonomy	218
<i>Eswaran Padmanabhan and Paul F Reich</i>	
Soils as archives of city history	232
<i>Hermine Huot and Jean Louis Morel</i>	
Classification of soils by ecozones	
Ecozones and soils – An introduction	246
<i>Rupert Bäumler</i>	
Cold Region Soils: Part I—Distribution, Properties and Processes	250
<i>Nicolas A Jelinski, Chien-Lu Ping, and John CF Tedrow</i>	
Cold region soils: Part II – Genesis and classification	263
<i>Nicolas A Jelinski, Chien-Lu Ping, and John CF Tedrow</i>	
Boreal forest soils	280
<i>Gabriele Broll</i>	
Soils of humid cool temperate regions	289
<i>Nicolas A Jelinski, Justin B Richardson, and Edward A Nater</i>	
Grassland soils in the cool–arid–temperate ecozone (Steppe, grassland)	299
<i>Mengyang You, Xiaobing Liu, Rupert Bäumler, and Margaret A Oliver</i>	
Soils from a warm-temperate semi-tropical ecozone (Mediterranean) with humid winter months	319
<i>J Torrent, Marco Pfeiffer, and Juan José Ibañez</i>	
Arid and semi-arid subtropical and tropical ecozone (II)	332
<i>Bernhard Lucke</i>	
Humid subtropical ecozone with emphasis on Acrisols and Alisols	343
<i>Nilton Curi, Sérgio Henrique Godinho Silva, and Alberto Vasconcellos Inda</i>	
Soils of the humid and sub-humid tropics	353
<i>Karl Stahr and Ludger Herrmann</i>	
Classification of soils by properties and environmental settings	
Sodic soils	368
<i>Guy J Levy and Uri Nachshon</i>	
Organic soils	383
<i>Heike Schimmel and Wulf Amelung</i>	
The pedology of anaerobic soils	398
<i>John Hollis and Allan Lilly</i>	
Alluvium and alluvial soils	417
<i>Janis L Boettinger</i>	
Hydric Soils	424
<i>MJ Vepraskas and JF Berkowitz</i>	
Wetland soils	436
<i>Cornelius Wilhelm van Huyssteen</i>	
Paddy soils: Characteristics, productivity and management	447
<i>Stephan M Haefele</i>	
Volcanic soils and non-volcanic andic soils	458
<i>Rupert Bäumler and G Uehara</i>	

PEDOMETRICS**Pedometrics**

Overview of Pedometrics	471
<i>Alexandre MJ-C Wadoux, Inakwu OA Odeh, and Alex B McBratney</i>	

Statistics and soil data analysis

Statistics in soil science	486
<i>Richard Webster</i>	

Multivariate analysis for soil science	499
<i>Si Yang Han, Patrick Filippi, Mercedes Román Dobarco, Januar Harianto, Mathew S Crowther, and Thomas FA Bishop</i>	

Machine learning and processing of large data	509
<i>Madlene Nussbaum</i>	

The issue of scale and change of support in the spatial analysis of environmental data	521
<i>A Castrignanò, A Belmonte, and N Romano</i>	

Soil measurements in space and time

Sampling for soil survey	535
<i>DJ Brus</i>	

Handling of soil samples in the field, in transport to the laboratory and in the laboratory	551
<i>Claudy Jolivet, Céline Ratié, Déborah Chavrit, Nicolas Soler-Dominguez, and Antonio Bispo</i>	

Digital Soil Morphometrics	568
<i>Yakun Zhang, Alfred E Hartemink, Jingyi Huang, and Budiman Minasny</i>	

Proximal soil sensing in the field	579
<i>Mikaela Tilse, Uta Stockmann, and Patrick Filippi</i>	

Proximal sensing of soil moisture	591
<i>Markus Tuller, Ebrahim Babaeian, and Scott B Jones</i>	

Proximal sensing of land surface temperature	600
<i>Ebrahim Babaeian and Markus Tuller</i>	

Proximal sensing of evapotranspiration	610
<i>Ebrahim Babaeian and Markus Tuller</i>	

Remote sensing of soil moisture	618
<i>Alexander Gruber and Jian Peng</i>	

Remote Sensing of Soil Organic Carbon	631
<i>Bas van Wesemael and Sabine Chabrilat</i>	

Pedotransfer functions and their application to soil water dynamics	642
<i>Marcel G Schaap, Yonggen Zhang, and Attila Nemes</i>	

Spatial and temporal soil variation

Geostatistics: Modelling spatial variation	655
<i>Richard Webster</i>	

Uncertainty assessment of spatial soil information	671
<i>Gerard BM Heuvelink and Richard Webster</i>	

Digital soil mapping: Evolution, current state and future directions of the science	684
<i>Brendan Malone, Dominique Arrouays, Laura Poggio, Budiman Minasny, and Alex B McBratney</i>	

Geographical information systems (GIS) and soils	696
<i>S Grunwald and J Böhner</i>	

Precision agriculture	710
<i>James A Taylor</i>	

Foundations, measurements and trends in pedodiversity <i>Juan José Ibañez and Marco Pfeiffer</i>	726
Soil landscape modelling	
Modeling soil development in a landscape context <i>Peter A Finke, Budiman Minasny, and Arnaud JAM Temme</i>	739

Abstract

Edaphology is the study of soil and soil organism relationships, and how these relationships affect plant growth. The study of edaphic factors is important in understanding the Earth's Critical Zone, the outer skin of our planet where rock, soil, water, air, and organisms interact to regulate the environment and support life. Edaphic factors are soil conditions and properties that affect the fauna, flora and microbial organisms living in the root zone, rhizosphere, or landscape. Such factors are numerous but the most important include water content, aeration, nutrient levels, pH, and soil temperature.

Glossary

Agroecology The science of applying ecological concepts and principles to the design and management of sustainable agroecosystems. See also: sustainable agriculture.

Base-cation saturation ratio (BCSR) A method of interpreting soil tests based on the relative ratio balance of the base cations (calcium, magnesium, potassium and sodium) that would be found in an ideal soil. This somewhat controversial method is used in some sustainable agriculture and some sectors of urban horticulture.

Ca²⁺ Calcium ion.

CEC Cation exchange capacity.

Climax The most advanced successional community of plants capable of development under, and in dynamic equilibrium with, the prevailing environment.

Earth's Critical Zone The near-surface, life-sustaining environment that includes living organisms, rock, soil, water, and air.

EC Electrical conductivity, related to the concentration of salts in solution or soil salinity.

Ecology The science of the relationship between organisms and their environment.

Edaphology The science that deals with the influence of soils on living things; particularly plants, including human use of the land for plant growth. The term may also refer to man's use of soil for plant growth or the overall human use of the land.

Gleyed/gleying A condition resulting from prolonged soil saturation and reducing conditions, indicated by the presence of bluish or greenish colors from ferrous iron in the soil mass or as mottles.

Humus Organic soil compounds exclusive of undecayed plant and animal tissues, their 'partial decomposition' products, and the soil biomass. The term is often used synonymously with soil organic matter.

K⁺ Potassium ion.

Macronutrient A plant nutrient found at relatively high concentrations (greater than 500 mg kg⁻¹) in plants; usually refers to nitrogen, phosphorus, and potassium, but may also include calcium, magnesium, and sulfur.

Mg²⁺ Magnesium ion.

mg kg⁻¹ Milligrams per kilogram of dry soil or plant material. Similar to parts per million (ppm).

Micronutrient A plant nutrient found in relatively small amounts (less than 100 mg kg⁻¹) in plants. These include boron, chloride, copper, iron, manganese, molybdenum, nickel, cobalt, and zinc.

mm Millimeters or 1 × 10⁻³ (0.001) meters. Used to define the length or diameter of soil particles, flora and fauna including plant roots, soil organisms, etc.

Mottles Spots or blotches of different color or shades of color interspersed with the dominant soil color.

NH₄⁺ Ammonium ion.

Pedology The science that deals with study of soils in their natural environment. The science generally includes soil formation (pedogenesis), soil morphology, and soil classification.

Physiography The study of the earth's natural features including land formation, climate, currents and distribution of life.

Rhizosphere The region of the soil that surrounds plant roots. This zone of soil serves as the interface of plant roots and the surrounding soil matrix. Microbial populations, plant roots, root secretions, soil water, soil air, and soil nutrients are dynamically linked in this region of the soil.

Root zone The zone of the soil profile penetrated by plant roots. In natural environments, the root zone is comprised of the upper portions of the native soil profile (mostly A and B soil horizons). In urban environments and other human-affected locations, the root zones are created from non-native soils or loose materials such as sand, clay and organic matter to meet specific construct criterion.

Sodium adsorption ratio (SAR) A relation between soluble sodium and soluble divalent cations that can be used to predict the exchangeable sodium fraction of soil equilibrated with a given solution. It is defined as the concentration of sodium divided by the square root of the sum of calcium and magnesium concentrations.

Soil salinity The salt content of the soil. Soil salinity is generally increased by the accumulation of salts from mineral weathering, water evaporation and/or application of saline irrigation water.

Soil quality/soil health The ability of a soil to support plant growth and development for human purposes based on the physical, chemical, and microbial characteristics of a soil. Improving and sustaining soil quality and soil health is a major principle of sustainable agriculture and organic production. In addition, soil organic management, crop rotations, mixed plant communities and cover crops are used to maintain a diverse soil microbial community, thus maintaining soil quality and soil health.

Sufficiency nutrient levels Traditional method for analyzing soil tests by determining the available soil nutrients that are found in sufficient levels for plant growth. Nutrients found in excess, or detrimental levels, are also addressed in this analysis technique. Also named Liebig's Law of the Minimum.

Sustainable agriculture The use of ecological principles to manage soil quality and soil health while cultivating plants for food, fiber and forage to sustain human life.

Worms m⁻² The number of earthworms per square meter of soil.

Key points

- Edaphology is the study of soil in relation to plant growth.
- Edaphic factors include the physical, chemical, and biological conditions of soil.
- Supporting flora and fauna is one of the major functions of soil.

Introduction

Edaphology is the study of soil and soil organism relationships, and how these relationships affect plant growth. The [Soil Science Society of America \(2008\)](#) defines edaphology as “the science that deals with the influence of soils on living things; particularly plants, including man's use of land for plant growth.” The root of the word is ‘édaphos,’ Greek for ‘foundation,’ ‘soil,’ ‘ground,’ or ‘land.’ ‘Soil science’ is the term more commonly used today and includes the study of soil as a natural body in the landscape (pedology), as well as a medium to be managed for optimum crop and rangeland productivity, environmental waste disposal, and construction. Cooperatively, pedology focuses on the description, classification, and formation of soil in place ([Richter, 2019](#)). Edaphology concentrates specifically on soil as a medium for fauna (animal), flora (plant) and microbial growth, or generally the human use and management of soil to grow plants.

The study of edaphic factors is important in understanding the Earth's Critical Zone, the outer skin of our planet where rock, soil, water, air, and organisms interact to regulate the environment and support life ([Committee on Basic Research Opportunities in the Earth Sciences, 2001](#)). Edaphic factors have been described as those soil conditions and properties that affect the fauna, flora and micro-organisms living in a particular root zone, rhizosphere, or even landscape. Such factors are numerous but the most important include water content, aeration status, nutrient levels, pH, and soil temperature ([Lindbo et al., 2012](#); [Weil and Brady, 2017](#)). Climatic or physiographic factors also influence living organisms, but these factors have a larger scale and tend to affect aboveground activities more than the below ground soil environment.

Ecosystems are thrown out of balance when major disturbances occur such as overgrazing of rangeland, or the conversion of native forests or grassland to agriculture (Brantley et al., 2006). Newly disturbed ecosystems cannot be adequately described by traditional theories of plant succession or climax models. The maintenance of agricultural land by humans prevents natural plant succession. An edaphic climax is a localized vegetative community that differs from the surrounding vegetation because of different soil types and properties, including water-holding capacity, drainage class, soil depth, and soil fertility. Nonequilibrium ecology and vegetation dynamics describe the interactions between the soil resource and the associated vegetative community. In these models, the condition of the soil is directly connected to aboveground vegetation. The organisms that live in a soil influence soil formation and are in turn affected by the edaphic properties that govern water, air, and nutrient supply. Thus, a continual feedback relationship is established between the soil flora and fauna, and the physical and chemical characteristics of the soil.

Soil is dynamic, teeming with organisms, and is an integral, interactive part of the environment. Soil is the foundation upon which our civilization stands, and it must be used wisely and conserved if we are to continue benefiting from its numerous functions, including food and fiber production, environmental protection, water and nutrient storage, and engineering roles.

Edaphology research

Studies conducted by ecologists, plant scientists, agronomists, and soil scientists (or edaphologists) are designed to measure, characterize, monitor, and assess the soil status as it serves as a medium for plant growth. Edaphology research is largely divided into ecologic and agronomic studies.

In the science of ecology, the spatial variation or distribution of vegetation as a function of soil type or edaphic property is important to characterize an ecosystem (e.g., Luo et al., 2021). The information gleaned from these studies provides a baseline of native vegetation in the landscape and helps identify changes due to anthropogenic and climatic effects. The long-term goal of this kind of study is to manage or protect native or desired vegetation by understanding the relationships among plant communities, the underlying soil, disturbance regimes, and physiographic features. Ecological studies that correlate plants with specific soil types, properties, or microbial activity in addition to landscape position and climate information are other examples of edaphology. Evaluating or predicting the effect of management on soil–plant interactions and edaphic factors is often the objective of studies on ecosystem health, soil status, and land degradation.

The second field of edaphology research focuses on agronomic management to maximize crop yields. Irrigation and soil-fertility management are examples of this approach. Agronomic edaphology is the study of agricultural foundational principles where long-term cropping practices are used to sustain soil fertility and productivity. Intensive conventional agriculture can deplete soil organic matter and beneficial microorganisms, thereby deteriorating soil status, reducing soil ecosystem functions and degrading the soil. Employing conservation practices may slow, halt or reverse negative impacts of intensive conventional agricultural management practices. By monitoring indicators of soil status and various edaphic factors, scientists can assess the usefulness and sustainability of adopted management practices on agronomic ecosystems (or agroecosystems) (USDA, 2020). The two broad areas of ecological and agricultural edaphology have also been combined to allow comparison of intensively managed agroecosystems with virgin soils and native vegetation.

Sustainable agriculture and organic production

The growing focus on sustainable agriculture and organic farming has heightened the awareness of edaphology and edaphic factors. The FAO definition of sustainable agricultural development is “the management and conservation of the natural resource base, and the orientation of technological and institutional change in such a manner as to ensure the attainment and continued satisfaction of human needs for present and future generations. Such development... conserves land, water, plant and animal genetic resources, is environmentally non-degrading, technically appropriate, economically viable and socially acceptable.” (<https://www.fao.org/3/u8480e/U8480E01.htm>). In the United States, sustainable agriculture is defined by U.S. Code Title 7, Section 3103, as amended in 2011, as “an integrated system of plant and animal production practices having a site-specific application that will, over the long-term – (a) satisfy human food and fiber needs; (b) enhance environmental quality and the natural resource base upon which the agriculture economy depends; (c) make the most efficient use of nonrenewable resources and on-farm resources and integrate, where appropriate, natural biological cycles and controls; (d) sustain the economic viability of farm operations; and (e) enhance the quality of life for farmers and society as a whole” ECFR (Electronic Code of Federal Regulations), 2011. This legal definition of sustainable agriculture differs from organic farming and various other soil management philosophies including ecological, regenerative, biodynamic, community-based, environmentally sensitive, extensive, low-input, permaculture, wise-use agriculture. Each of these terms has a slightly different perspective, but they all have similar goals, which is to ensure that plant yields are maximized without harming the soil. Successful management practices are intended to further improve soil status with time.

Sustainable agriculture focuses not only on the sustainability of the means of production, including the land and other resources, but also the economic sustainability of agricultural system. On the other hand, organic production identifies specific, restricted agricultural practices that cannot be used for the agricultural products to be classified as organic. To be considered an organically

produced agricultural product in the United States, they must not have been grown with synthetic- and petroleum-based products or other prohibited practices during crop production and handling. U.S. Code Title 7.B.I.M.205.105, as amended in 2021 (<https://www.ecfr.gov/current/title-7/subtitle-B/chapter-I/subchapter-M/part-205/subpart-B/section-205.105>), requires the product to “have been produced and handled without the a) use of synthetic chemicals and ingredients, . . .; b) nonsynthetic substances prohibited . . .; c) nonagricultural substances used in or on processed products . . .; d) nonorganic agriculture substances used in or on processed products . . .; e) excluded methods, except for vaccines: *Provided*, That the vaccines are approved. . .; f) ionizing radiation, as described in Food and Drug administration regulation . . .; and g) sewage sludge.” Although the rules for organic production in the European Union are lengthier and more specific, they follow the spirit of the US guidelines (https://eur-lex.europa.eu/legal-content/EN/TXT/?uri=uriserv:OJ.L_.2018.150.01.0001.01.ENG&toc=OJ:L:2018:150:TOC). Regardless of the depth and scope of the regulation policies, sustainable agriculture, organic production and other soil management philosophies use edaphological practices to ensure the soil will provide long-term benefit to the farmers and society. Balancing the soil physical, chemical, and biological properties for the benefit of the crop increases the plant’s ability to produce and the land’s ability to support humanity.

The production and consumption of organic produce has increased since the 1990’s, resulting in the organic market becoming one of the fastest growing sectors of agriculture. The overall U.S. agricultural market share for organic fruit and vegetables was 15% in 2019 (Willer et al., 2021). Increased acceptance and consumption of organic produce will likely continue to grow. In addition to the elimination of petrochemicals and synthetic fertilizers from their management practices, organic farmers place an emphasis of “soil health” or “soil quality” to increase yields of produce. However due to the restrictions on synthetic pesticides, increased pest management efforts and additional human labor are often required to produce desirable yields. Soil health and soil quality in this context refer to the status or ability of a soil to support plant growth and development for human purposes based on the beneficial integration of soil physical, chemical, and microbial characteristics (Doran et al., 1994).

Edaphic properties

Edaphologists study the soil by examining a variety of factors or soil properties that govern life in the soil. Edaphic factors include those physical, chemical, and biological properties of a soil that influence plant growth. The various properties that are important for plant growth are interrelated but can be distilled to a few simple requirements. Essentially, what plants need from the soil are water, air, nutrients, and physical support. Sunlight is required for photosynthesis but is provided aboveground and may be affected by aspect, latitude, and other physiographic and climatic factors.

Edaphic factors affect the ability of soil to sustain biological production and diversity, regulate and partition water, filter and buffer contaminants, store and cycle nutrients, and provide plant support. Generally, soils of better status will provide a superior growing environment for plants, resulting in plants of greater quality with increased productivity. Also, beneficial microbial soil communities will flourish in such soils. When soils function well in supporting plant growth, they are considered to be fertile and productive but also resist erosion, and help maintain good air and water quality. Soils that are resilient to natural and anthropogenic stresses are therefore resistant to degradation. Farmers, homeowners, turfgrass managers and other managers of the land can use a variety of management practices to produce and sustain soils. These best management practices result from edaphic research and include supplementation of root zones with composts, manures, and other organic amendments; utilization of cover crops and crop rotations; application of integrated pest management practices, including biological pest control methods. Soil quality or health indicators are those physical, chemical, and biological properties that measure a soil attribute or function and are sensitive to changes in environment and management (Tables 1–3) (Doran et al., 1994).

Table 1 Some physical edaphic properties and soil status indicators that affect plant growth by influencing water and air movement, plant rooting and soil microbial activity.

<i>Soil property</i>	<i>Water and air movement</i>	<i>Plant rooting</i>	<i>Microbial activity</i>
Texture (sand, silt, and clay)	X	X	X
Structure (especially porosity and macropore arrangement)	X	X	X
Bulk density (dry mass/bulk volume)	X	X	X
Soil depth or distance to impermeable layer	X	X	
Drainage class	X	X	X
Water-holding capacity (related to texture and structure)	X		X
Infiltration (water movement into the soil surface)	X		X
Hydraulic conductivity (water movement through the soil)	X		X
Soil-water potential (or availability of water)	X		X

Table 2 Some chemical edaphic properties and soil status indicators that affect plant growth by influencing water and air movement, nutrients, or rooting depth in soil.

<i>Chemical property</i>	<i>Water and air movement</i>	<i>Nutrient availability</i>	<i>Rooting</i>	<i>Microbial activity</i>
pH		X		X
Cation exchange capacity		X		X
Organic matter content	X	X	X	X
Nitrate nitrogen		X		X
Organic nitrogen		X		X

Total or soluble potassium		X		X
Micronutrients		X		X
Clay mineralogy	X	X	X	
Salinity or EC	X	X		X
Toxic ions or heavy metals		X		X

Table 3 Some biological edaphic properties or soil status indicators that affect plant growth by influencing water and air movement, nutrients, or rooting depth in soil.

<i>Biological property</i>	<i>Water and air movement</i>	<i>Nutrient availability</i>	<i>Root support or impedance</i>
Earthworm number	X	X	X
Respiration rate (measure of microbial population and activity)	X	X	
Microbial diversity	X	X	
Composition of organic matter	X	X	X
Plant root depth	X	X	X

Edaphic factors affecting water and air

Soil physical properties have the greatest effect on water movement into and through the soil. The role of water is so important in plant growth that some definitions refer to edaphology as the science of physics applied to soil and water. Water and air are considered together because they use the same pathways to enter and move through the soil (Hillel, 1998). The water-holding capacity of a soil refers to the amount of water contained in a soil and is determined largely by texture, structure, porosity, organic matter content, and depth (Weil and Brady, 2017).

Soil texture refers to the particle-size distribution of the inorganic soil material which ranges over at least three orders of magnitude from sand (2–0.05 mm) to clay (<2 μm) sizes. Soil texture and structure (the arrangement of particles) both have a direct impact on soil porosity, a property that reflects the number and size of pores in the soil (Weil and Brady, 2017; Lindbo et al., 2012). In general, finer-textured clayey soils and soils with larger organic matter content will have greater total porosity than coarser-textured sandy soils or soils with less organic matter. Even though clayey soils have greater porosity and hold more total water than sandy soils, the water is held so tightly in the micropores that more of it is not available to the plants. The micropores prevalent in clayey soils store water in the root zone for a longer time but greatly resist its movement through the soil because of their small cross sectional area and interconnectivity. In addition the water is subject to a higher matric potential acting (the attractive force of a solid for water). Sandy soils, on the other hand, have large, interconnected macropores that fill and drain easily. Macropores provide for water and air movement through the soil, but do not hold water very long in the root zone (Fig. 1). While the texture refers specifically to the distribution of particles less than 2 mm in diameter, also known as the fine earth fraction; another valuable piece of information is the percentage of gravel or amount of particles greater than 2 mm. The larger particles affect soil packing, porosity, bulk density, nutrient status, and root growth.

Porosity results from the arrangement of soil particles into aggregates with inter- and intra-aggregate pores, as well as from root growth and faunal activity. Macropores can form after roots decay or as a result of burrowing by soil fauna. One of the most dominant groups of soil animals are earthworms, which may number from approximately 50 to 300 worms m^{-2} in agricultural soils up to 500 worms m^{-2} in forest and grassland soils. Earthworms shred and consume organic matter and excrete wastes as casts, which help create stable soil aggregates and enhance soil porosity (USDA, 2020). Their burrows are persistent over time and provide a major conduit for drainage and preferential water movement through the soil, but also minimize surface water erosion by increasing infiltration. In agricultural soils, the presence and abundance of earthworms often indicate, productive, organic-rich soils (Stroud, 2019).

Bulk density is the dry soil weight per volume of soil and is a good measure of porosity and compaction. Generally, uncompacted soils containing 50% pore space with a bulk density of 1.1–1.6 g cm^{-3} are ideal for agricultural soils. Soil minerals have an average particle density of $\sim 2.65 \text{ g cm}^{-3}$. Pore space is included in the volume of a soil but the air content does not weigh

Fig. 1 The size and amount of pores in sand and clay results in different bulk densities and water holding capacities.

much, thus as porosity increases, the dry weight decreases for a given volume, resulting in a lower bulk density. Compacted soils have large bulk densities ($1.5\text{--}1.8\text{ g cm}^{-3}$), few macropores, and tend to restrict root growth, water and air flow. Texture and organic matter both affect bulk density as well. Sandy soils have a larger bulk density than clayey soils because of smaller total porosity. Organic matter weighs very little, takes up a large volume, and so creates lower bulk density. Some minerals have a large particle density (mass per particle volume) and can contribute to a greater soil bulk density if they are dominant in the soil. Soils with a smaller bulk density contain more plant available water than soils with a large bulk density, but they tend to drain quickly and become droughty (Fig. 1).

Organic matter contributes to water-holding capacity in several ways. It aggregates soil and produces a crumb-like structure at the surface that facilitates infiltration, percolation, storage, and diffusion of water and air. Sticky substances, such as waxes and tannins left behind when soil organisms decompose organic residues, help bind soil particles together into porous clusters that hold and release water, nutrients, and humus. Soil organic matter or humus holds as much as 20 times its weight in water and has many beneficial physical, chemical, and biological properties (Magdoff and Van Es, 2021). The O and A horizons in soil profiles have the largest amounts of organic matter and are often measured in field studies to evaluate their influence on nutrient supply or relationship to vegetation. Organic carbon or total organic matter is also commonly measured in edaphic studies. Too much organic matter can cause other problems due to the waxy coating left on coarse textured soils, such as those 80–100% sand golf course putting greens, that results in hydrophobic soils with decreased infiltration rates despite the dry soil conditions. Naturally occurring water-repellent soils are found in other parts of the world where sandy soil particles become coated in plant waxes or other plant degradation products (e.g., see <https://www.csiro.au/en/research/plants/crops/farming-systems/water-repellent-soils>). Once dried, organic matter is often hydrophobic and may repel water.

The depth of the soil and the water-holding capacity also directly determine the total amount of water present. Many trees and desert shrubs have root systems that exploit soil water and nutrients to depths below 2 m, but most agronomic plant roots are concentrated in the upper meter of the soil. Urban root zones are often shallower. Water movement through a root zone is hampered by any changes to soil physical properties including changes in texture, compaction, porosity or organic matter content. The bottom of a soil profile may be an impermeable layer or hardpan, bedrock, or a shallow groundwater table. Shallow, eroded soils hold less water than deep, uniformly textured soils. Gleying and mottles are evidence of water-saturated soil and poor aeration or anaerobic conditions prevailing for extended periods of time.

Mineralogy, specifically the kind and amount of certain clay minerals, may also affect water and air movement through the soil. Some well weathered soil minerals such as montmorillonite, a member of the smectite family, absorb water and swell to fill up cracks and macropores, resulting in restricted hydraulic conductivity. This is particularly problematic in sodic soils or alkali-affected areas. Sodium (Na) is a cation with low charge density and therefore has a greater hydrated radius than higher valency ions, that tends to neutralize and disperse negatively charged clay particles and the aggregates formed from clay and organic matter. When aggregates disperse, they form an impermeable seal at the soil surface and along cracks that limits the movement of water and air into the soil (Fig. 2). Other problems with salinity are discussed in a later section.

Fig. 2 Infiltration and percolation is enhanced by well-structured soil aggregates while dispersed clay particles in sodic soils may cause ponding.

Edaphic factors affecting plant nutrients

For optimum growth, plants require many inorganic nutrients in varying amounts and forms. Macronutrients have concentrations of at least 500 mg kg⁻¹ in plants, while micronutrients are required in much smaller amounts, usually less than 100 mg kg⁻¹. Nitrogen (N), phosphorus (P), and potassium (K) are the most commonly measured and applied macronutrients by farmers, gardeners, and other land managers. Macronutrients are not necessarily the most important nutrient in determining the ability of that plant to grow; macro- refers to the large quantity used by the plant. Liebig's Law of the Minimum (or sufficiency levels) describes the fertilizer needs of plants by stating that plant growth (yield) is controlled by the most limited (needed) nutrient. In other words, an application of the most limited nutrient in the form needed by the plant will result in additional plant growth. The next most limited nutrient will then control the rate of growth of the plant. The exact requirements of each nutrient vary for each plant and environment. Recommended ranges are determined through edaphology research and experience.

Fertilizers are labeled with their N-P-K amounts and should be applied to the soil only when soil or tissue test results indicate that the nutrients are below optimum levels. Fertilizer applications for nutrients that are not limiting will not result in additional growth and may leave the plant root zone by leaching or runoff impacting offsite environments. Due to the rapid fluxes of soil nitrogen content, on-site tissue tests for nitrogen are often more accurate than soil tests. Specific edaphic factors that may be measured to monitor soil fertility include nitrate-N, available P, and soluble K (Table 2). Other commonly measured nutrients include calcium (Ca), magnesium (Mg), sulfate (SO₄²⁻), and iron (Fe). Recent debates in the scientific community have considered not just the total amount of each nutrient affecting plant growth and plant landscape distribution, but also the relative proportions of nutrients. Base-cation saturation ratio (BCSR) has been considered an important tool for determining soil health in sustainable agriculture and some sectors of urban horticulture. For example, the calcium-to-magnesium ratio may be used to explain the occurrence of some endemic plants growing on serpentine soils in California, USA. However, other research has found higher plant health results when the minimal nutrient levels for sustainable growth are used in fertilizer programming (Woods et al., 2016).

The soil reaction or pH is related to nutrient availability and optimum plant growth. Soil pH is one of the most common and important soil chemical properties measured. Some plants prefer acidic soils, while others are best suited for alkaline soils. There are few plants that will survive in extremely acid or alkaline soils however, and most flora and fauna prefer conditions between pH 5.5 and 8.5. For most plants, having soil pH close to 6.5 is ideal as all essential plant nutrients are very available. Some pH-based nutrient problems can be avoided with the use of foliar-absorbed nutrients. Soil pH also affects the soil microbial population necessary to mineralize soil organic matter to inorganic nutrient forms.

The combined physical, chemical, and biological benefits of organic matter make it one of the most important edaphic factors affecting plant growth (Magdoff and Van Es, 2021). Most microbes prefer warm, moist, near-neutral pH conditions to mineralize organic matter. These conditions produce an active microbial community that will decompose manure, compost, and plant residues into their final inorganic products of carbon dioxide, water, and plant-available inorganic nutrients. The nutrients found in these sources are generally found in smaller quantities and are more slowly available to the plant than those in manufactured inorganic fertilizers. Soils rich in organic matter are darker and tend to warm up faster in the spring. For these reasons, management of soil organic matter is essential for those practicing sustainable agriculture and organic production.

The ability of a soil to adsorb or hold cations is called the cation exchange capacity (CEC). Soil organic matter and clay minerals are usually negatively charged, thus allowing them to attract and retain positively charged cations from the soil solution. This is an important feature of soil materials because many plant nutrients are cations (e.g., potassium (K⁺), calcium (Ca²⁺), magnesium (Mg²⁺), ammonium (NH₄⁺) and many micronutrients). Cations are held loosely and temporarily by negatively charged exchange sites in and around soil particles that prevent leaching with every rainfall or irrigation event. However, their attraction is not permanent and the cations are easily available to plants and microbes as conditions allow. Soils that have abundant humus and smectite or vermiculite clays have larger CEC than sandy soils with little organic matter (Weil and Brady, 2017). Organic matter is also valuable in complexing or chelating some metals to make them more soluble and plant-available. In addition, soil organic matter has been shown to negate the toxicity of aluminum (Al) in some soils.

Several elements are toxic to plants and may require characterization to determine whether they are affecting plant growth and distribution on the landscape (Table 4). Aluminum, nickel (Ni), manganese (Mn), lead (Pb), copper (Cu), chromium (Cr), and cobalt (Co) are among the metals that have been analyzed and correlated with vegetation growth around mines or smelters. Some elements are plant micronutrients at low concentrations but become toxic at high concentrations in the soil or solution. Examples of these elements are boron (B), Cu, Mn and zinc (Zn). In addition, excessive quantities of some nutrients can result in deficiencies in other nutrients due to preferential uptake (Ackova, 2018).

Soil mineralogy also influences the availability of some important nutrients such as phosphate and sulfate (Weil and Brady, 2017). Allophane or clay materials derived from volcanic glass can fix or permanently adsorb phosphate and sulfate anions. Iron and aluminum oxides are prevalent in leached, acidic soils of humid zones and can combine with phosphate to make insoluble phosphate minerals that are unavailable to plants. In arid regions, where calcareous soils are common, the calcium combines with and binds the phosphate. Phosphorus is generally most plant-available at near-neutral pH and in soils not dominated by allophane, iron or aluminum oxides, or calcium carbonate. Available or extractable phosphorus is analyzed to distinguish it from organic or mineral forms that are not accessible to plants.

Potassium and ammonium may also become "fixed" or unavailable in soils high in vermiculite. The size of these ions and their charge density allow them to become permanently imbedded in the interlayer region of high-charge vermiculite clay minerals that

Table 4 Toxic elements that may affect plant growth and soil status.

<i>Trace element</i>	<i>Maximum concentration allowed in irrigation water^a (mg L⁻¹)</i>	<i>Essential to plants at low concentrations?^b</i>
Aluminum (Al)	5.0	Probably not
Arsenic (As)	0.10	Probably not
Beryllium (Be)	0.10	No
Bismuth (Bi)	NA	No
Boron (B)	NA	Yes
Cadmium (Cd)	0.01	No
Chromium (Cr)	0.10	Probably not
Cobalt (Co)	0.05	Probably not
Copper (Cu)	0.20	Yes
Fluorine (F)	1.0	Probably not
Iron (Fe)	5.0	Yes
Lead (Pb)	5.0	Probably not
Lithium (Li)	2.5	Probably not
Manganese (Mn)	0.20	Yes
Molybdenum (Mo)	0.01	Yes
Nickel (Ni)	0.20	Yes
Selenium (Se)	0.02	Probably not
Silver (Ag)	NA	No
Tin (Sn)	NA	No
Vanadium (V)	0.10	Probably not
Zinc (Zn)	2.0	Yes

NA, no maximum concentration has been designated.

^aCriteria established by the Food and Agricultural Organization (FAO, 1985) of the United Nations.

^bSome elements are required by plants at low concentrations but are toxic at higher levels (therefore 'Yes'), and some elements are still under investigation or only partially accepted as being essential, thus the term 'Probably not', but as of 2021, these are more likely to be 'No', but there are no updated universally accepted lists published.

collapse around them in response to opposite electrical charges. Thus, soluble potassium or clay mineralogy is measured to determine the amount of K available for plant uptake.

Salinity, often measured by electrical conductivity (EC), can be a problem in closed basins with shallow water tables, arid regions where evapotranspiration rates exceed precipitation rates, and in areas with poor quality irrigation water. Inorganic fertilizers are also salts and may contribute to soil EC and saline stress when applied in excess. Salinity refers to all ionic compounds in a soil solution while sodicity refers specifically to the Na concentration relative to calcium and magnesium concentrations. Not all salts are equally destructive to plants and soil. For example, while Na may disperse clay aggregates, forming an impermeable seal at the soil surface and along cracks that limits water and air movement into the soil, high Na levels can also be toxic to plants and impede water movement into plant roots. The sodium adsorption ratio (SAR) or exchangeable sodium percentage (ESP) are two measures of the sodium content affecting plant growth, especially when rainfall is insufficient to leach salts out of the soil profile. Closed basins with shallow groundwater are often sodic, saline, and detrimental to plant growth (Hopmans et al., 2021).

Salts can affect plant growth in two ways, either directly as a toxic specific ion or indirectly by lowering the osmotic potential of the soil water, which hinders the plants' ability to uptake water. Increased salts lower the osmotic potential, which in turn lowers the total soil-water potential and requires additional energy to extract water from the soil solution (Hopmans et al., 2021). Specific ion toxicity can be a problem when B, chloride (Cl), selenium (Se), or Na concentrations are excessive. Some plants are especially adapted to salinity. Adaptations include ion selectivity to prevent absorption of toxic ions through roots, sequester toxic ions into plant tissues or organelles away from critical plant tissues and plant functions, osmotic adjustment in plant tissues to ensure normal enzymatic activity, and osmotic adjustment in the rhizosphere to improve water uptake from soil matrix.

Edaphic factors affecting root and microbial growth

Many of the edaphic factors previously discussed affect plant root growth and development. Water or air movement and nutrient availability are linked to the growth of plant roots. In addition, beneficial microbial communities are found in larger quantities when the associated plants are healthier. Plant root development, microbial activity, and edaphic factors are strongly correlated (e.g., Yao et al., 2018). Additional edaphic factors that can also directly impact rooting and microbial growth are discussed below.

Soils having extremely large or small bulk density are not beneficial for microbial activity or plant growth. Compaction and high bulk density limit the root system due to the limited pore space and reduced pore space continuity for unimpeded development. Therefore, plants must use additional energy to push their roots through the soil to access more soil water and nutrients. Limited

porosity also reduces water and air movement which limits both root and microbial growth. Consequently, the symbiotic relationship of soil microorganisms and plant roots is weaker (Gregory, 2006; Weil & Brady, 2017). Conversely, in soils with extremely low bulk density, the application of moderate compaction may enhance plant growth by increasing contact between soil and developing roots. Microbial activity may also be enhanced by closer proximity to the soil water and nutrients.

Soil temperature is an important edaphic factor, influencing plant growth and root development but has limited impact on air movement in soil and moderate impact on plant nutrient availability. Soil temperature is affected by several physical properties including porosity, water content, soil color, organic matter content, bulk density, and soil depth. Temperature is also a function of location in the landscape and physiographic features such as aspect, elevation, and latitude. Agriculture management practices that moderate soil temperature vary by region, time of year, and crop.

Shallow soils resulting from wind and water erosion are problematic for proper root growth of most desirable plants. Agricultural management practices should be employed to minimize soil loss, especially between crops when the soil is most exposed to the weather. The maintenance of good plant cover year-round is one of the best ways to minimize soil loss, and thus is an important component in soil conservation and management. Physiographic factors such as slope percentage, aspect, and location on the landscape are often recorded along with edaphic factors to evaluate plant–soil–landscape relations.

Most urban soils are shallow and contain a smaller root zone volume than needed by the plant. In addition, these soils may serve a utilitarian purpose, such as a drivable surface for emergency traffic or temperature moderation to reduce urban heat island effects. The soil conditions surrounding homes and other edifices are usually not ideal because of the loss of topsoil and displacement of deeper soil horizons during construction. These newly exposed soils will contain smaller concentrations of organic matter and less diverse microbial communities. Due to soil limitations and other urban hazards, urban plants have shorter life spans than those same plants found outside urban centers. However, with continued plant growth, organic matter inputs and careful management, these soils can become more favorable for future plants and microorganisms.

Conclusion

Edaphology is the study of the soil as a plant growth medium. To support healthy, high functioning ecosystems, one needs good soil conditions in which to grow the necessary flora and fauna. Soils serve a variety of functions in the environment and are a reusable, but not a quickly renewable resource. Edaphology research provides guidance on the management of this precious resource for both agronomic and ecologic functions.

Abstract

Soil biodiversity contributes to ecosystem services such as nutrient cycling, water filtration, pest control, carbon storage, and soil stabilization, all important for human well-being. Diversity in the soil ranges from the microbes to vertebrates that sometimes use soils for only part of their lives. Scientists use many tools to study soil biodiversity depending on the organisms being studied. Recently molecular techniques have been employed to understand global distributions and changes in soil biodiversity. Many factors affect biodiversity, including organic material and climate. Understanding the threats to biodiversity is important for conservation of this vital resource for life on Earth.

Key points

- Soil biodiversity provides many ecosystem services that support other life on Earth including human well-being including nutrient cycling, water filtration, and soil fertility.
- The diversity in soil is very high, ranging from soil microbes to invertebrates and vertebrates.
- Understanding the distribution of soil biodiversity globally is challenging and many different techniques are used for this, including molecular techniques.
- Many factors influence soil biodiversity, including climate and organic material.
- Understanding emerging threats is key to conserving soils for human health and well-being.

Introduction

Soils teem with life. Representatives of almost every phylum of organism known aboveground also occur in soil. In less than a handful of soil, there can be millions of types of microbes and hundreds of species of microscopic invertebrates. The identities and natural histories of these microscopic flora and fauna and many of the larger, visible soil fauna are the least-known biota in terrestrial ecosystems. However, new evidence is rapidly revealing the major contributions of soil organisms to the maintenance of life on Earth, opening a new frontier for exploration and a rising concern about the loss of soil biodiversity with increasing degradation of the soil habitat locally and globally. Soil biota regulate numerous ecosystem processes. Their activities provide a wealth of essential ecosystem services for humans, such as breaking down organic matter, filtering water, stabilizing soil, generating and renewing soil fertility, providing nutrients for plant growth, modifying the hydrologic cycle (including mitigating floods and controlling erosion), and controlling pest and pathogens of plants and animals. Plants, soil biota, and their consumers are tightly coupled and increasingly soil organisms are recognized for their influence on broader ecological functions such as productivity, decomposition rates, patterns of biodiversity and global change (Table 1). Soil biodiversity influences ecosystem processes in all ecosystems, terrestrial and aquatic including the atmosphere, through regulation of CO₂ flux and carbon sequestration in soils. Understanding how soil biodiversity will change and as a consequence, alter ecosystem functioning as fertile soils continue to decline globally is important knowledge for policymakers and members of the public who need to develop and implement strategies for the future.

Diversity and abundance

Soil biodiversity includes a plethora of life that is hidden from our everyday view: viruses; bacteria; actinomycetes; fungi; algae; protists (single celled eukaryotes); microscopic invertebrates such as rotifers, tardigrades (water bears), soil planaria (flatworms),

Table 1 Estimated diversity and abundance of soil taxa based on published literature and supported by expert judgment.

Taxon	Diversity per amount soil or area (taxonomic units indicated below)	Abundance (approximate)
Bacteria and Archaea	100–9000 cm ⁻³	4–20 × 10 ⁹ cm ⁻³
Fungi (including mycorrhizal fungi)	200–235 g ^{-1a}	100 mg ⁻¹
AMF (species)	10–20 m ⁻²	81–111 m cm ⁻³
Protists (sequences)	253–961 g ^{-5b}	10 ⁴ –10 ⁷ m ⁻²
Nematodes (genera)	10–100 m ⁻²	2–90 × 10 ⁵ m ⁻²
Enchytraeids	1–15 ha ⁻¹	12,000–311,000 m ⁻²
Tardigrades	NA	490 mg ^{-1c}
Collembola	20 m ⁻²	1–5 × 10 ⁴ m ⁻²
Mites (Oribatida)	100–150 m ⁻²	1–10 × 10 ⁴ m ⁻²
Isopoda	10–100 m ⁻²	10 m ⁻²
Diplopoda	10–2500 m ⁻²	110 m ⁻²
Earthworms (Oligochaeta)	10–15 ha ⁻¹	300 m ⁻²

^aOperational taxonomic units.^bGeisen et al. (2015).^cCzernerková et al. (2015).

and nematodes (roundworms); the microarthropods, Acari (mites) and Collembola (springtails); and larger invertebrates, easily seen by the naked eye such as terrestrial gastropods (snails and slugs), isopods (pill bugs, sow bugs), Oligochaeta (enchytraeids and earthworms), spiders, scorpions, beetles, centipedes, millipedes, crustaceans, ants, and termites. Because of this diversity, the invertebrates are frequently grouped by size (body width) as microfauna, mesofauna, and macrofauna (Orgiazzi et al., 2016; Fig. 1). Vertebrates also depend on the soil as a habitat, for example, moles, prairie dogs, meercats, wombats, small rodents, and some species of lizards, snakes, frogs, and even birds. Many aboveground invertebrates may be temporary inhabitants (such as nematode parasites of insects; immature Diptera such as tipulid crane flies and tephritid fruit flies; cicadas; and Coleoptera such as

Fig. 1 A simplified soil food web representing the substantially more complex real-life food soil food web that includes many other groups of soil fauna. From Nielsen UN, Wall DH, and Six J (2015) Soil Biodiversity and the Environment. *Annual Review of Environment and Resources* 40: 63–90.

scarab beetle) living in the soil for only one stage of their life cycle or occurring seasonally. Thus, soil diversity is dynamic and tightly connected to the aboveground biotic and climatic systems.

It appears that billions of bacteria, meters of fungal hyphae, and millions of protozoa, nematodes, oligochaetes, and arthropods can inhabit a square meter of soil (Table 1). The diversity of these species appears so immense that knowledge of the numbers of species (species richness) in just two groups, the microarthropods and nematodes, could substantially increase overall global biodiversity estimates. Yet our understanding of the total numbers of soil species even within any one group is surprisingly poor. Data suggest 90–95% of soil biota are unidentified and unknown to science. There is no single location where the total number of all soil species or molecular types of microbes, invertebrates, or vertebrates has been assessed, although up to 1000 invertebrate species have been enumerated by traditional methods in a square meter of forest soil. Global estimates have been based on many studies of varying numbers and sizes of soil samples from a variety of ecosystems and generally only to shallow (0–20 cm) depths. Unfortunately, this leads to an underestimate of soil biodiversity given that mites and nematodes occur to 15 m depths in deserts and bacteria and nematodes to greater depths elsewhere. Nonetheless, global estimates of the total numbers of species identified morphologically from soils (Fig. 1) include 600 species of enchytraeids, 1500 species of soil protozoa, 5000 species of nematodes, and 20,000–30,000 species of mites (Freckman and Virginia, 1989).

Even with the enormity of soil biodiversity, there is excitement about the species yet to be identified and their role in ecosystems. Advancements in technology such as molecular tools, biochemical methods, and microscopic advancements (scanning electron microscope, image analysis) are enabling faster identification or characterization of organisms. For example, many studies now use new molecular technologies to measure both microbial (Fierer and Jackson, 2006) and eukaryotic biodiversity and compare assemblages quantitatively among sites. Examples of the eukaryotes include soil arthropods (Oliverio et al., 2018) and earthworms (Decaëns et al., 2013). By examining multiple gene regions, researchers can simultaneously assess and compare functional (e.g., diversity of protein-coding gene categories), phylogenetic and taxonomic diversity of soil communities. Advances in bioinformatics allow comparisons among huge molecular datasets as well as identification of soil organisms to standardized taxonomic levels (van den Hoogen et al., 2019). Stable isotope technology has improved analysis of the contribution of different groups of taxa to carbon and nitrogen flow in the soil food web. Scientists, distributed globally with expertise in specific soil biotic groups, have increased evidence of the number of species and what they do in an ecosystem, by sharing data, images and results via the internet, and creating web pages for the public.

These new methods, when combined with traditional methods, are accelerating knowledge of belowground biodiversity and ecosystem functioning. However, there are few taxonomists and systematists remaining who specialize in the identification, natural history, and phylogenies of the soil biota. Specialists that are versed in the techniques for collecting, extracting, and identifying the various organisms provide essential information for analysis of different ecosystems, but there are no standard techniques for the collection or extraction of even a single group of fauna. For example, a handful of soil might suffice for extracting and identifying many species of microscopic nematodes, mites, protists, and microbes, but a different technique would be required for identification of earthworms. Technology, new educational and data analysis tools, better training and the excitement of conquering these challenges are attracting students to this new frontier of science (FAO et al., 2020; Orgiazzi et al., 2016).

Distribution

Soils, like air and water, are resources that have developed over geologic time and are non-renewable in our lifetime. Both the type of soil and the evolutionary adaptation and dispersal mechanism of an organism to a particular location play a role in establishing the structure of a soil biotic community. Soil chemical and physical factors combine to make each soil a unique habitat. Chemical (e.g., pH, salinity, type and amount of organic matter and nutrients) and physical properties (e.g., texture -amount of sand, silt, and clay, pore size, moisture, temperature) along with the composition of vegetation and geologic history, all contribute to the evolution of the diversity of species in soil. These components are all intertwined, and changes in any one factor can result in a new habitat for the biota. For example, an increase in organic matter can also increase the soil water-holding capacity, which tends to result in a darker soil that will have higher soil temperatures. Soil texture is also linked to microclimate. As clay content increases, soil fertility, soil moisture, and soil temperature can increase. Clay content is in turn largely dependent on the parent material (granite related to sandy soils versus limestone related to clayey soils) or landscape position (a floodplain is more fine-grained, a ridge top more coarse-grained). Thus, beneath our feet, there are thousands of soil habitats due to many combinations of factors such as pH, fertility, organic matter, soil moisture, climate, and geologic history.

Soil biota occupy remarkably different habitats within the soil with some species living only in decaying leaves and dead wood, or in the rich organic matter horizon, while others occur several centimeters to meters deeper in the mineral soil (Coleman et al., 2017). For example, some species of earthworms occur in litter-organic horizons and others exist in deeper mineral soil. Species of organisms may be very different even at millimeter scales near a growing root than further away in bare ground. Increasing to larger scales, within a backyard or agricultural field, the diversity (species richness) might be similar. However, comparison of an agricultural field to a nearby natural area will generally show a very different community. At a global scale, primary factors affecting the biogeography of soil organisms are climate, the type (trees, grasses, forbs) and amount of vegetation (organic matter), and soil texture (composition of sand, silt, and clay). But these can vary with the type of organism, for example a primary factor for the distribution of nematode functional groups is soil carbon (van den Hoogen et al., 2019). In general, microarthropod-rich soil

communities are found in forest ecosystems which have lower soil pH, root biomass, mean annual temperature, low soil inorganic N and higher C:N, litter and moisture than grasslands. Hot and cold desert ecosystems have lower levels of diversity than forest, grassland or tundra ecosystems. For example, earthworms are generally absent from dry ecosystems, illustrating an evolutionary adaptation to moist soils (Phillips et al., 2019). Bacterial diversity appears unrelated to site temperature, latitude, and other variables used to predict plant and animal diversity and instead correlates strongly with soil pH (Fierer and Jackson, 2006). A growing focus on using computer learning and in modeling diversity, abundance and activity of soil microorganisms across the globe is providing some perspective to help scientists characterize community-level and regional understanding of how soil organisms affect carbon storage and where to concentrate efforts to mitigate effects of climate change and biodiversity loss (Crowther et al., 2019). As data are compiled on organisms and their natural history and then combined with geographic information systems (GIS) maps of soil and vegetation, reliable estimates of the global biogeography of soil microflora and fauna will become feasible.

Dispersal mechanisms of biota are a key to their distribution at local, regional, and global scales. Soil organisms are transported with soil: by humans transporting plants or by cars, trucks, or other machinery; in rainwater, floods, seawater; carried externally and internally by animals such as birds, ungulates, and insects; in plant debris; and by wind. Protists, rotifers, tardigrades, and nematodes are aquatic biota, living in water films around soil particles, but as soil dries, they enter a dormant state, anhydrobiosis (meaning life without water), reduce their body surface area, water content, and metabolism, and can live for years until they revive in water. While in anhydrobiosis, they can be wind-transported over hundreds of miles. Collembola live in air pores of soil and in organic matter and were long thought to be confined to small geographic areas. However, they are now known to survive and move to other continents in seawater, because of a physiological advantage, their hydrophobic (unwettable) cuticles. This finding on a new means of dispersal will accelerate hypotheses on the global distribution patterns of Collembola. Other dispersal mechanisms are based in geologic time. For example, earthworm distribution in North America has been patterned largely by glaciation.

Soil biodiversity and ecosystem functioning

Soil organisms moderate numerous ecosystem processes (e.g., decomposition, C and N transformation, hydrologic cycles) that are a major component of global cycles. Land-use change, climate change, pollution, desertification and an increase in invasive species are all components of 'global change': whether global change results in the resilience or alteration of species composition within the soil community, and how this may impact ecosystem function, are important questions in the research of soil biology today. Little knowledge exists about the functional attributes of the majority of individual species, but there is considerable information on the consequence of larger species on soil processes. Macrofauna (earthworms and termites) species have a significant effect on soil structure and hydrology, and transfer and reconfigure organic matter, affecting nutrient mobility. The influence of these animal species on surface-soil plant litter can be measured at local and larger regional scales, but for smaller species, scientists have used other approaches to determine their influence on ecosystem processes. Scientists lump species with similar morphologies and feeding sources into functional groups and measure the transformations of carbon and nitrogen through each functional group within the soil food web. A couple of examples illustrate this in the following paragraphs.

Perhaps some of the greatest diversity is involved in the decomposition (decay) component of the soil food web. In natural terrestrial ecosystems, the bulk of the world's dead plant material (leaves, stems, dead roots, also known as detritus) falls to the ground to be decomposed. The rate of decomposition in an ecosystem is affected by climate, the quantity and quality (type or chemical composition, generally C, N, and lignin) of the substrate or detritus (leaf versus wood versus animal material, for example), and a 'detritivore' functional group in the soil food web that includes many species of generalist feeders from numerous phyla. If the substrate is more recalcitrant (has more lignin or a larger C:N ratio, e.g., wood of trees) decomposition will occur primarily by fungi and fungal consumers. If the organic matter is more labile (less lignin or smaller C:N, ratio e.g., some grasses) bacteria and their consumers generally are the major decomposers.

The breakdown of detritus is a product of a succession of the species of invertebrates and fungi, actinomycetes and other bacteria, all with specific roles in decaying complex organic substrates into inorganic nutrients that are then available for plant growth. For example, some faunal species (e.g., arthropods) shred leaves into smaller particles; others channel through the soil, increasing the distribution of microbes and the organic matter while affecting soil porosity in the soil profile; other fauna ingest the pieces of organic matter, further exposing it to enzymes that aid the decay, and then pass it from their bodies in a different chemical form. Smaller microscopic animals, nematodes, mites, and Collembola prey on the decomposers, bacteria and fungi, maintaining them in an accelerated growth phase, accelerating the transfer of nutrients to soil. As with other biotic food webs, predators are at the top of the soil food web. Interestingly, predators in soil food webs can be microflora (e.g., fungi that prey on nematodes) and microfauna (predaceous nematodes, or mites or tardigrades feeding on nematodes), as well as macrofauna. Understanding predator-prey relationships of species can contribute to biocontrol management of soil pathogens of humans and plants.

Aboveground and belowground taxa are tightly coupled ecologically and interactions between them are known as plant-soil feedbacks (Nielsen et al., 2015). For example, species with mutualistic symbionts such as mycorrhizal fungi can enhance access to limiting nutrients, with a positive feedback on productivity. Alternatively, the accumulation of pathogens or root herbivores in early successional soils may weaken pioneer plant species and pave the way for later successional stages through negative feedbacks.

Invasive plant species can produce chemicals that reduce local mycorrhizal fungi or promote soil pathogens more harmful to surrounding native species than the introduced species. The theoretical framework around these feedbacks will help explain the dynamics and succession of vegetation, the invasiveness of introduced species in new habitats and how terrestrial ecosystems may respond to land use and climate change.

Global change and impacts on soil biodiversity

Land-use change is the major driver affecting soil biodiversity and future soil sustainability. Land-use changes (tillage, pollution, paving with concrete, erosion, dams, change in plant species) affects soil physical and chemical properties, soil structure, and the base of the soil food web (chemical composition of plants, amount of organic matter, manure) and thus have direct impacts on species composition. The conversion of a natural grassland or forest to a managed system for agriculture, pasture, urban, or industrial use changes the determinants of soil biodiversity, the vegetation, soil structure, and microclimate. The disruption to the natural vegetation and the soil habitat with land-use change decouples the nutrients provided by the decomposition food web from plant uptake. The result is a loss in soil fertility provided by the original soil and its inhabitants. Additional fertilizer is required, and pesticides may be necessary especially with more intensive agriculture because the new soil food web generally has fewer predators, resulting in a change in or loss of biocontrol of plant pathogens (Tsiafouli et al., 2015). While conservation tillage methods are beneficial in conserving carbon in soils and creating a food web that is more detritus-based, often a lower level of herbicides and pesticides is used. There are examples from tropical wet and dry forests, grasslands, deserts, and other ecosystems showing that these land-use changes affect the total soil biota (macrofauna, microfauna, and microflora), generally reducing species diversity. Desertification resulting from land-use change has a considerable impact on soil processes, including reduction of soil carbon, soil structure, soil biota, and soil fertility.

Invasive species of plants and animals also influence changes in soils and biotic communities. The movement of plants, people, and machinery has not only increased the numbers of species invasions into soils globally, but has significantly increased impacts on soil biodiversity and some characteristic of the ecosystem (e.g., nutrient cycling, species richness and or abundance, plant factors, soil physical or chemical factors) and increased costs of eradication. In some cases, freedom from native pathogens, root parasites and herbivores allow introduced plant species to proliferate in a new habitat. Furthermore, invasive species often influence surrounding biodiversity through negative plant soil feedbacks. An earthworm species introduced to New York has changed forest-floor litter quality and composition, soil chemistry, and water infiltration rates. European nations are examining ways to eradicate the New Zealand planarian flatworm, *Artioposthia triangulata*, a predator of earthworms. This invasive species has impacts aboveground (removing the food source for birds) and belowground (removing an animal species that influences organic matter transformation, soil hydrology, and structure). Invasive plant species with differing rooting depths and plant chemical composition can have repercussions for soil communities. Woody plant invasions into grasslands of the Great Plains of the USA have greater rooting depths (affecting soil carbon storage) and, at these depths, a more depauperate nematode community.

Increasing levels of CO₂ and climate change (temperature and rainfall patterns, and extreme, infrequent events such as droughts and flooding) indirectly affect soil biodiversity through impacts on plant community composition or soil chemistry. Soil biota play a crucial role in terrestrial carbon cycling, and can be sensitive to climate change. Although data vary with ecosystem, modifications in the soil community and changes in belowground herbivory and decomposition pathways for soil food webs have been documented. Even in the Antarctic Dry Valleys, where there are no visible plants, climate change has decreased soil nematode populations through changes in temperature and available soil water. At a global scale, warmer, wetter conditions associated with climate change will result in altered distributions of aboveground taxa with unpredictable consequences for soil biota. Due to the differing abiotic controls acting on aboveground and belowground diversity, their response to climate change will likely differ temporally and in magnitude. Since these systems are intricately linked together, decoupling of aboveground/belowground diversity may result in overall lower productivity and reduced diversity. Direct effects of elevated CO₂ are considered to be less important, since soils have high ambient levels of CO₂ owing to root and microbial respiration.

Changes in rainfall are now known to disrupt the balance between the abundance of root-feeding nematodes in grasslands, which are major constraints to ecosystem primary production, and their predators in favor of the root feeders (Franco et al., 2019). These nematode responses increase in magnitude from arid to moist grasslands, and further aggravate the effects of drought on grassland primary productivity and above-belowground plant biomass partitioning (Franco et al., 2020).

Soil food webs can be modeled to simulate the loss of species due to global change and to examine the effect, if any, on nutrient cycling and plant production. For example, in the short grass steppe of Colorado, USA, a model was assembled using field data on the microbes and micro- and mesofauna (Hunt and Wall, 2002). A single factor global change scenario (elevated CO₂) and resulting change of plant species composition, which might indirectly result in the loss of soil biodiversity, was simulated for each of the 15 functional groups in the soil food web. For example, loss of bacteria and fungi led to extinctions of other groups in the soil food web. Removal of six of 15 groups impacted the abundance of other groups, and three of these groups (bacteria, saprophytic fungi, and root-feeding nematodes) caused up to a 10% change in two ecosystem processes, nitrogen mineralization, and plant primary production. More recently, studies show that multiple global change factors acting simultaneously affect soil communities and the processes they control that is unpredictable from single- or two-factor studies (Rillig et al., 2020; Thakur et al., 2019).

Soil food web models may not reflect the complexity of individual species interactions and the underlying habitat but are critical for scientific analysis and forecasting for future scenarios of C and N cycling. The C and N cycling of the soil food web ties the soil to

the aboveground ecosystem by relating the soil biota to soil carbon storage, nutrients available for plant growth and to atmospheric CO₂ and trace gas fluxes. Models, along with studies at species and functional group resolution, are currently being examined in experiments that manipulate biodiversity in field, laboratory (microcosms with generally less than 10 species), and in large soil experiments in plant growth facilities. Together these provide a theoretical and quantitative basis for integrating the soil biota into global ecosystem studies.

Sustaining soil biodiversity

Soil biodiversity is an important resource that regulates ecosystem processes essential to the functioning of earth's ecosystems. Our understanding of the species, their interactions, and effect on processes occurring in the soil food web in natural systems are an important contribution to management of land, particularly agriculture. The link between aboveground and belowground diversity is strong, although occurring at different temporal scales for organisms, and changes affecting aboveground diversity and function are reflected in belowground ecosystems. An immediate effect is a decrease in the biological capacity of soils and a change in the regulation of interactions and processes. Knowledge on whether all or a few key taxa are important in this regulation of ecosystem processes is a high priority for planning for future sustainability.

Current priorities in the study of soil biodiversity include: (1) understanding the functions of rarely sampled fauna so that species estimates and global distributions are based on an accurate and current database; (2) determining which habitats are most vulnerable for soil biodiversity loss, e.g., where the 'hot spots' of biodiversity are, and which habitats and what time frames are most amenable to restoration; (3) synthesizing data and determining which invertebrate and microbial 'species' are key to ecosystem processes; (4) identifying gaps in knowledge of multispecies interactions, including plant soil feedbacks and their influence on ecosystem functioning; (5) collaborating on long-term (more than 3 years) experiments to examine effects of global changes on aboveground-belowground biodiversity linkages and ecosystem functioning; (6) determining, based on natural history information, which species are more likely to be invasive if introduced, and using this information as a management tool to reduce spread and identify threats to other species and (7) predicting the effect of a warmer wetter planet, brought about through climate change, on resilience of soil biodiversity and function. Given advancements in methods for assessing soil biodiversity, and by building upon current knowledge, mapping and assessing soil biodiversity from regional to global scales is now possible. Continued research into soil biodiversity is essential if we are to measure the effect of the many threats and determine options to conserve this vital resource for human health and well-being.

Abstract

Viruses are an essential component of soil biodiversity and contribute to important ecosystem functions. In the past, soil viruses have been largely understudied due to methodological challenges of extracting viruses from the complex soil environment. This has gradually changed with the availability of recent metagenomic analysis. In this chapter, we revisit phage diversity and life strategies, introduce recent advances in utilizing metagenomic methods to characterize soil phages, and summarize the potential roles of soil phages in mediating biogeochemical element cycles and plant health by influencing their microbial hosts. Finally, we discuss the feedback responses of soil phages to global changes and highlight the importance of incorporating the roles of soil phages into global biogeochemical models.

Glossary

Auxiliary metabolic genes (AMGs) Phage-contained genes that can modulate host metabolism and improve host fitness. Phages often obtain those genes from their hosts via horizontal gene transfer.

Bacteriophages (phages) Viral particles that infect bacteria, accounting for the largest proportion of virosphere in the natural environment.

Microdiversity Intra-population genetic variation. The viral microdiversity in natural environments is largely underexplored.

Phyllosphere The aerial part of a plant, harboring diverse microbes on the surface and within the plant organs. Phyllosphere microbiome is critical to plant growth.

Prophage A temperate phage that can lead to a lysogenic infection, integrate its genome into host chromosome and replicate in conjunction with host genomes.

Superinfection exclusion A phenomenon that a primary phage infection can protect hosts via preventing the replication of a second infection by a closely related phage.

Total soil metagenomes A culture-independent and sequencing-dependent approach to study soil microbiome, which extracts and analyzes DNA of all entities from soil sample.

Viral ecology The studies focusing on viral abundance, community composition, biogeography, host prediction and their potential ecological functions.

Viral shunt A process during which hosts are lysed by phages and host biomass is transferred into available nutrients (i.e., dissolved organic matter) for neighboring microorganisms, with consequences for global biogeochemical cycles.

Viromes Viral metagenome that is retrieved using a series of procedures including size-fractionation to remove most cellular contamination, concentration of virus-like particles, and extraction of viral DNA.

Key points

- Phages have enormous morphological and genomic diversity and diverse life strategies.
- Metagenomic approaches have radically improved our understanding of soil viral ecology.

- Soil phages play an important role in carbon and other biogeochemical cycles.
- Soil phages are critical to plant nutrient uptake and health through modulating plant associated microbial communities.
- Global changes have important consequences for soil phage diversity and potential ecological functions.

Introduction

Viruses are highly diverse and ubiquitous in the environment. They can infect every cellular organism and are recognized as a critical component in food web ecology. *Viral ecology* has been widely studied in marine systems where viruses are known to be instrumental in a range of ecological functions through infecting and regulating marine microbial communities. For example, viruses lyse approximately 20–40% of marine prokaryotes, acting as a control of host abundance and community compositions. During the viral lysis process, nutrients are released from host cells, with important consequences for global element cycles (Breitbart et al., 2018). Viruses can also reprogram host metabolism and modulate biogeochemical cycles through expressing auxiliary metabolic genes (AMGs) that are involved in a wide variety of metabolic functions and can extend the ecological niches of hosts during infection (Hurwitz and U'Ren, 2016). Marine viruses are also known to drive microbial evolutionary trajectories, through their co-evolution with hosts or functioning as major horizontal gene transfer agents.

It is highly plausible that cell infection by soil phages and subsequent cell lysis also regulate soil microbial community diversity and composition, thereby influencing soil processes, in a manner similar to the one described for marine ecosystems. The heterogeneous soil environment provides diverse microhabitats for organisms (e.g., bacteria, archaea, fungi, protists, and fauna) and supports an enormous diversity of viruses. Bacteria are the predominant component of soil organisms and viruses associated with them (*Bacteriophages/phages*) are generally the most abundant group of the virosphere. As metagenomic analyzes are being refined (i.e., *total soil metagenomes* and soil viromes), they are beginning to provide deeper insights into soil viral community composition and diversity, and their roles in regulating host populations and evolution dynamics and nutrient cycles (Sommers et al., 2021). Recent viromic studies demonstrate the potential ecological importance of soil phages in impacting soil carbon cycling process. Soil phages may also influence plant nutrient acquisition and act as bio-control agents of bacterial pathogens in agroecosystems. However, the underlying mechanisms of those processes require further exploration.

In this chapter, we revisit phage morphological and genomic diversity and their potential life strategies, summarize the current major state-of-the-art methods for studying the diversity and functions of soil phages, and outline current knowledge of viral contribution to soil element cycling and their potential roles in plant growth and health. In the context of global change, a large body of studies investigating climate warming, extreme weather, acidification, flooding or other changes, are revealing the effects on soil microbial communities and their feedback responses (Eisenhauer et al., 2012; Dubey et al., 2019). Here we further discuss the responses of soil viral diversity and function to global changes and highlight the theoretical and practical importance to incorporate soil phages into global biogeochemical models.

Diversity and life strategies of phages

Morphological observations with transmission electron micrograph classify phages into several types according to their capsids (protein shell), including polyhedral (e.g., *Microviridae*, *Corticoviridae*), pleomorphic (e.g., *Plasmaviridae*), filamentous (e.g., *Inoviridae*), and tailed particles (e.g., *Caudovirales*). Among those, the *Caudovirales* order of tailed phages includes *Siphoviridae*, *Myoviridae*, *Podoviridae*, *Ackermannviridae*, and *Herelleviridae*, and represents the most isolated and characterized phage group. Phages have various genome types, including double-stranded DNA (dsDNA), single-stranded DNA (ssDNA), single-stranded RNA (ssRNA), and double-stranded RNA (dsRNA) (Sommers et al., 2021). The dsDNA genomes of tailed phages account for the largest proportion of phage genomes in the public databases. Traditionally, the International Committee on Taxonomy of Viruses (ICTV) classified phages according to their genome structure, morphology diversity, and host range. This method, however, can only characterize a limited number of phage taxa as the vast majority of phages cannot be cultivated under laboratory conditions. Recent application of culture-independent metagenomic approaches revealed a more comprehensive picture of the virosphere and identified an extremely high viral diversity from natural environments. For example, an analysis of ~5 Tb metagenomic sequence data from more than 3000 global samples revealed over 125,000 partial DNA viral genomes, which led to a 16-fold expansion in the number of known viral genes (Paez-Espino et al., 2016). Viral genomes include a great proportion of unclassified and uncovered viruses, comprising >90% in some samples. It remains a great challenge for the ICTV to establish guidelines for robust classification of rapidly emerging unknown phages.

To identify uncultivated phages, which can provide unprecedented insights into the virosphere, the ICTV has included genomic features as a fundamental component of taxonomic classification. A 15-rank classification hierarchy has been developed to explore viral macroevolution and establish evolutionary relationships among distantly related viruses (International Committee on Taxonomy of Viruses Executive Committee, 2020). Virus taxonomy keeps dynamic to accommodate new discoveries of viral lineages (Dutilh et al., 2021). Some studies have clustered viral genome sequences into unique

viral operational taxonomic units (vOTU), based on genome similarity, to capture evolutionarily and ecologically cohesive units and assess viral genomic diversity. This classification, however, may sometimes conflict with ICTV-ratified taxa. Studies based on the vOTU analysis have tried to link viral diversity parameters with different biomes, locations, niches, or abiotic and biotic factors to reveal how viruses interact with their surrounding environments, enabling us to identify the key environmental drivers of phage community and distribution patterns. For example, soil viral communities showed temporal dynamics and were significantly correlated to soil properties (e.g., pH, soil organic matter, soil nutrition) in agricultural soils (Santos-Medellin et al., 2021).

Soil phages have diverse replication strategies, typically including lytic, lysogenic, and chronic. During lytic infection, hosts are lysed by virulent phages with virus progeny and cellular lysates being released into the environment. Phages that only initiate lytic infection are termed “virulent phages”. In lysogenic infections, phages integrate their genomes into host chromosome or maintain them extrachromosomally. They can replicate without lysing hosts and no viral progeny is released outside of host cells. Temperate phages are able to enter into either a lysogenic or lytic lifestyle, and the switch is influenced by many factors, including hosts and phages (e.g., gene, host density, and superinfection), the environment (e.g., temperature, nutrient levels, salinity, and other environmental stresses) and other external signals (e.g., quorum sensing signaling molecules) (Correa et al., 2021). Specifically, according to the “kill the winner model” (Thingstad, 2000), lytic life cycles are generally favored when host abundance is high, whereas lysogenic infections are more common when host densities are low, enabling survival in an unfavorable environment. This view, however, is challenged by the finding that weak or even negative correlations are observed between the frequency of phages and host density in some habitats, such as coral reefs and mammalian gut, which supported the proposal of the “Piggyback-the-Winner” model (Knowles et al., 2016).

Phages can also initiate a chronic life cycle, during which progeny virus particles are released into the environment from host cells without killing their hosts. This life cycle has been mainly identified for the *Inoviridae* family which is detected widely in aquatic, terrestrial and host ecosystems, indicating the widespread environmental prevalence of chronic life cycle. In addition, other lifestyles also exist, such as “pseudolysogeny”, during which phages remain in the host cells as an extrachromosomal element (Chevallereau et al., 2022). The pseudolysogeny lifestyle may be associated with host starvation and phages are unable to replicate due to the low energy state of hosts. When environmental conditions favor host cells, productive cycles of phages may develop. However, which infection type of phages prevails in soil remains unclear, and it is important to understand phage infection strategies for prediction of their interactions with hosts and ecological roles. As soil is a heterogeneous environment and soil microorganisms and phages may experience environmental fluctuations over a short period, phage-host interaction in situ may be extremely complicated and dynamic. Phage lifestyle is traditionally determined by laboratory experiments, but this can be labor-intensive and seems impossible for the continuous discovery of newly uncultivated viruses. Some computational methods have been developed to predict phage lifestyles, e.g., PHACTS, PropagATe and BACPHLIP. The accuracy and universality of those methods awaits to be verified with more environmental sequence data and experiments.

Advances in methodologies to study soil viruses

Metagenomic methods (e.g., total soil metagenomes and viromes) have been increasingly used as an instrumental approach to study soil viral ecology. The total soil metagenomic method directly obtains metagenomic sequences from free phage particles, soil organisms (bacteria, archaea, fungi, and other eukaryotes), and lysogenic-state prophage. It can link the potential performance of phages with their host community composition and metabolic functions. In particular, DNA stable isotope probing (SIP) technique can be combined with metagenomic approach to identify active linkages of phages and hosts from the individual to population level. For example, a recent DNA-SIP-metagenomic study linked phages to a critical biogeochemical process of methane oxidation, and revealed active interactions of phages with hosts at different trophic levels including both methylotrophs and non-methanotrophic methylotrophs (Lee et al., 2021). H_2^{18}O SIP-metagenomics were used to track all viral activities and virus-host dynamics, and identify their ecological roles in frozen northern peat soils (Trubl et al., 2021). This method requires expensive isotopically labeled substrate to ensure sufficient labeled nucleic acids as the failure rate of labeling viral metagenomes may be relatively high. As a promising tracing method, it could be widely applied in the future to decipher the mechanisms of the roles of soil phages in targeted processes (e.g., nitrogen fixation and organic matter degradation).

The virome method requires a number of steps (e.g., size fractionation and centrifugation) before DNA extraction to eliminate cellular contaminants and ideally extract sequences from virus like particles (VLPs). Compared with the soil total metagenomes method, viromes recover a higher proportion of viral data (especially the rare virosphere) and reduce the difficulty of assembling viral sequences (Santos-Medellin et al., 2021). It is increasingly becoming an important method to investigate phage communities and their involvement in ecosystem functions. Soil virome procedures include the following major steps (Fig. 1) (Bi et al., 2022). Soil samples (~50–500 g) are mechanically or artificially mixed with elution media to release free phages from the soil. Elution media containing VLPs are concentrated using tangential flow filtration (TFF), polyethylene glycol concentration or centrifugal ultrafiltration. Some studies add a CsCl gradient ultracentrifugation purification step after concentration. Samples are then treated with DNase to remove free cellular DNA before extracting nucleic acids of phages. Amplification of viral nucleic acids is usually

Fig. 1 Soil virome experiments and analysis workflow. Soil virome experimental procedures generally include extracting and concentrating VLPs from soil suspensions, VLPs purification, and DNA extraction; viral metagenomic analysis mainly includes sequence quality control and assembly, viral consequence prediction, viral community composition and function annotation, and virus-host prediction. Specific methods and examples of computational tools are shown in green box.

required for metagenomic sequencing as viral genomes are small and DNA yield sometimes is extremely low. Optimized extraction protocols have been recently developed to extract dsDNA phages from agricultural soils (Goller et al., 2020). However, some issues of soil virome method remain: (i) the normal use of 0.2 μm threshold to remove large soil particles or prokaryotic and eukaryotic cells could deplete giant viruses, which are important components of virosphere; (ii) potential strong absorption of viruses to soil matrix hinders us from describing the full content of soil virosphere; and (iii) there is no standard procedure for bioinformatic analysis for phage identification, phage abundance, and gene function prediction.

The new single-virus genomics (SVG) method can characterize individual phage genetic information and genomic *microdiversity* within phage populations (Martínez et al., 2020). This method requires small amounts of samples. The procedures generally include collecting phages from samples, fluorescently staining dsDNA phages, separating or sorting individual phage particles based on fluorescent signals, lysing virion capsids, extracting and amplifying phage DNA, as well as sequencing and analyzing metagenome data. This approach can reconstruct and uncover genetic heterogeneity in phage population and potentially assembles genomes from variant-rich sample, which may be discarded during the assembly process of the metagenomic methods. However, SVG has poor detection of ssDNA and RNA viruses and has a relatively high cost. This method is now commonly used for marine samples but has been used in only a few soil studies, as the complex soil matrix leads to the difficulties with the fluorescent stain and VLPs separation. A representative example is the use of fluorescence activated cell sorting to separate potential nucleocytoplasmic large DNA viruses (NCLDVs) from forest soil. Combined with mini-metagenomics, it greatly expanded the phylogenetic diversity of NCLDVs (Schulz et al., 2018). Other sequencing technology—long-read sequencing e.g., Oxford Nanopore Technologies (ONT) and Pacific Biosciences (PacBio), can yield large assembly-free genomes and recover more complete viral genomes. The long-read sequencing combined with Illumina short sequencing has been used to reveal agricultural slurry viromes (Cook et al., 2021). That study reported a temporal-stable and lytic-dominated slurry phage community, which encodes abundant AMGs including virulence-associated genes and antimicrobial resistance genes. In addition, some other tools are capable of describing phage-host interactions and viral dynamics and overcoming some limitations in metagenomic methods. For example,

bioorthogonal noncanonical amino acid tagging (BONCAT) combined with metagenomics, nanoscale secondary ion mass spectroscopy (NanoSIMS), single-cell colony, PhageFISH, and Virocell-FISH can be used to better characterize soil virosphere and viral ecology (Sommers et al., 2021).

Potential roles of soil phages in the terrestrial ecosystem

Contribution of soil phages to biogeochemical element cycles

Phages can impact biogeochemical element cycling via top-down control through lysing microbial hosts. This process can transfer microbial biomass into dead particulate organic matter and dissolved organic matter (*viral shunt*) and impact microbes that drive biogeochemical cycles. Phages can also impact biogeochemical element cycling via bottom-up control through carrying and expressing AMGs and modulating host metabolisms (Trubl et al., 2018). Some pioneer studies investigated the roles of soil phages in carbon cycling processes. Viral sequences were retrieved from soil metagenomes, size-fractionated metagenomes, and viromes of permafrost peatlands (Emerson et al., 2018). Virus hosts were predicted in silico and a certain proportion of predicted hosts were linked to key carbon-cycling microorganisms related to methane production and oxidation and organic matter degradation. Divergent AMGs associated with central carbon metabolism, polysaccharide binding and soil organic matter degradation were also identified in the viral genomes. Among those AMGs, active function of one viral glycoside hydrolase was further expressed and verified with enzymatic assays (Emerson et al., 2018). Virus-contained AMGs related to carbon cycling are also observed in other soil habitats (e.g., agricultural soils and mangrove soils) (Jin et al., 2019; Bi et al., 2021), suggesting that viral involvement in carbon cycling process may be prevalent in the terrestrial environment.

Soil phages can also influence other nutrient cycling processes through lysing functional microbes and encoding AMGs related to sulfur, phosphorus or nitrogen cycling. The underlying mechanisms of why and how phages encode host-derived genes remain largely unknown. The well-studied AMGs include *psbA* and *psbD*, encoding core photosynthetic reaction centers, which are carried by cyanophages in the marine environment. Expression of *psbA* and *psbD* genes during infection process can promote the photosynthetic activity of hosts to generate energy for viral production and increase viral abundance. Some researchers further proposed that AMGs may maximize soil phage reproductivity by improving host fitness under temperate conditions or increase the chance of phage reproductivity by aiding their host survival under harsh conditions (Hwang et al., 2021). Despite the ecological importance of AMGs, there are great knowledge gaps in the diversity and proportion of AMGs carried by soil phages and under what conditions they are activated and expressed in microbial hosts.

Potential roles of soil phages in plant nutrient uptake and adaption

Plants provide various niches (e.g., rhizosphere, endosphere, and phyllosphere) for a wide spectrum of microorganisms. Some eukaryotic viruses (emerging as plant pathogens) are harmful to plant health and may cause crop diseases and yield decline. Phages mainly infect bacteria and modulate soil- and plant-associated bacterial community assemblies and turnover, thereby they can be beneficial, neutral or pathogenic to plants. Potentially, beneficial phages may increase plant nutrient uptake, mitigate environmental stress, and protect plants from pathogens via direct and indirect impacts on microorganisms within the soil food webs (Fig. 2). For example, phage-induced release of available carbon and other nutrients from bacterial cells is prevalent in the rhizosphere, which benefits plant nutrient acquisition (Fig. 2). However, the phage-induced mortality of beneficial bacteria that have plant growth promotion functions would impede plant nutrient acquisition. For example, phage lysis of *Rhizobium* bacteria and phosphate solubilizing microorganisms can negatively impact beneficial microbial functions and decrease plant nitrogen and phosphate acquisition. The *phyllosphere*, as the aboveground plant part, is subjected to environmental stresses (e.g., temperature change, drought, UV radiation, and nutrient deficiency). In such a harsh environment, phyllosphere bacteria may tend to be infected by temperate phages with lysogenic cycle and establish mutualistic host-phage relationships. Prophages may encode tolerance featured AMGs (such as DNA-repair proteins against radiation) or other AMGs supporting host metabolisms. The presence of those phages potentially improves the resistance of phyllosphere bacteria to the changing environment and promotes host survival under harsh conditions. Contradictory circumstances also remain that phage-encoded virulence factors (e.g., toxin, invasion and motility) can increase pathogenic bacteria infection of plants and have the potential to spread the virulence genes via horizontal gene transfer.

In addition to direct effects on plants, phage-host interactions indirectly influence plant growth. For example, the lysis of competitors of plant growth-promoting bacteria (e.g., inefficient soil rhizobia) may promote niche-competitiveness and early colonization by beneficial bacteria (e.g., efficient soil rhizobia), thereby facilitating later plant nitrogen acquisition (Fig. 2). Some phages can infect bacteria with lysogenic lifestyle and protect hosts against subsequent phage infection, which to some extent improves bacterial competitive fitness compared with other bacteria. As soil bacteria can evolve to escape viral infection and phages counter-adapt to this resistance, their co-evolutionary dynamics drive bacterial phenotypic and genotypic variation. The change in microbial community structure might have cascading effects on other microbiomes within the soil food web. In addition, root exudates may help the formation of mutualistic plant-virus association to increase plant fitness for nutrition acquisition or disease suppression. To date, however, plant-bacteria-phage interactions have been largely overlooked. Future studies are greatly needed to decipher the linkages among plant, bacteria, and phages and to reveal the roles of soil phages in plant-soil systems, which can promote the application of viruses for improving plant health and productivity (Pratama et al., 2020).

Fig. 2 Phages directly and indirectly influence plant growth and health. Phages in the rhizosphere soil potentially promote plant nutrient uptake via “viral shunt”; beneficial phyllosphere bacteria may be infected by prophages which can improve host fitness, thereby improving plant adaption to environmental stresses. Phages as an important biocontrol agent can protect plant by infecting and lysing bacterial pathogens. The phage-host interactions may have negative or positive impacts on plant growth by modulating bacterial competition and their functional performance within the food web.

Potential roles of phages in regulating crop health

Bacterial pathogens are known to cause great crop yield losses globally, representing a major threat to crop health and productivity. To reduce economic loss and ensure food security, multiple agricultural management practices (e.g., application of copper-based pesticides, antibiotics) have been widely applied to protect crops against bacterial pathogens. However, some bacterial pathogens have evolved to resist to the widely used agrochemicals and the agrochemical-based methods have unintended environmental and human health risks. Environmentally friendly control strategies are urgently required to ensure sustainable agricultural production. Phages can selectively infect pathogenic strains and propagate along with their hosts, and thus they are regarded as a potential biosafety and biosecurity biological control agent, compared with chemical options. Phage therapy (generally termed when used in human and animal protection) or phage biocontrol (generally applied term, when used in plants protection) was firstly proposed and applied in the early 20th century, but was hindered by the long-term and wide use of antibacterial agents. Most studies showed promising effects of phages on controlling pathogens, reducing disease incidence and promoting plant survival in the field or greenhouse conditions (Holtappels et al., 2021). One well-studied example is the application of phage biocontrol to combat the pathogenic bacterium *Ralstonia solanacearum* in the tomato rhizosphere (Wang et al., 2019). Four model lytic phages, belonging to the order *Caudovirales*, were isolated from four geographically distant tomato fields across China. The combination of those phages reduced pathogen densities in both greenhouse and field experiments, changed microbial community composition and diversity, and enriched bacteria antagonistic toward *R. solanacearum* in the rhizosphere.

It remains a great challenge to develop efficient biocontrol strategies in agricultural production through harnessing the potential of soil phages. Phages with an exclusive lytic (virulent) life strategy are more suitable than temperate phages in biocontrol, because temperate phages may replicate as part of host genomes without lysing bacteria, improve pathogenic host fitness and virulence, and even spread virulence genes to benign bacteria. In addition, it should be noted that *superinfection exclusion* induced by phages during their infection can prevent secondary infection of hosts by other phages. An ideal phage for biocontrol would have a relatively wide host range, which allows them to infect most targeted pathogen genera or species. Alternatively, a complementary set of isolated phages (i.e., phage mixture, cocktails) can be used to improve the efficiency of eliminating bacterial pathogens. Despite great potential of phage biocontrol in sustainable agriculture, development of efficient phage-based biocontrol products under fluctuating environmental conditions is still in its infancy.

Feedback responses of soil phages to global changes

Global changes, including warming, soil acidification, extreme drought, heavy precipitation and flooding, and land-use change, present grand challenges to the sustainable provisions of ecosystem functions and services. In particular, global temperature is predicted to rise continuously in coming decades and will lead to a significant increase in the frequency and intensity of extreme weather events. Many studies have reported that global changes influence the diversity and composition of soil microbial communities, with important consequences for their mediated functions. For example, microbial metabolic rates normally increase with temperature, and climate warming can alter soil microbial community compositions and functional genes in various terrestrial habitats (e.g., glacier forefield, forest and grassland) (Jansson and Hofmockel, 2020; Wang et al., 2020). A global meta-analysis based on 1235 observations found that global change factors have inconsistent impacts on microbial diversity, with rare microbial species being more vulnerable to global changes than common species (Zhou et al., 2020). As phages have intimate relationships with bacterial hosts, they are inevitably subjected to the changes in these abiotic factors. Variations in temperature, soil moisture, local geochemical properties, and host community can affect the infection, lifestyle, abundance, community composition, and functions of soil phages as well as their interactions with hosts. Among those global change factors, effects of temperature on phage infection have been well documented in laboratory and field experiments. Before reaching a phage-specific thermal optimum (T_{opt}), temperature increase is predicted to shorten the latency period and enhance the release of phage progeny, but a reversal trend is observed beyond the T_{opt} (Wieczynski et al., 2021). Temperature change (e.g., a slight increase) might induce changes in viral life strategies, switching from a lysis to chronic lifestyle which supports the coexistence of phages and hosts in unfavorable situations. Seasonal dynamics of phage abundance have been observed in agricultural and forest soils (Roy et al., 2020). However, in general, patterns of temperature-driven shifts in phage infections, lifestyles and abundance are complex and remain to be elucidated in natural environments, especially under the scenarios of combined biotic and abiotic factors.

To determine the impacts of warming on soil viral community composition, studies have sampled soils from simulated warming experiments established in a boreal peatland and found that viral community composition was significantly affected by soil depth, water content, and concentrations of methane and carbon dioxide, but not by temperature (Ter Horst et al., 2021). This insignificant effect of temperature on soil viruses might be due to the short time of only two-years for the warming treatment. Global warming results in the thawing of permafrost soils, leading to a shift of “soil-like” viral populations in drier soils to ‘aquatic-like’ viral populations in wetter soils. Viral communities are significantly related to host community composition, pH, soil moisture content, and soil depth, indicating that global change factors such as warming may alter viral populations through modulating soil properties and host communities (Schulz et al., 2018). Soil pH can modify the adsorption of phages to soil organic materials and minerals and influence the survival and infectivity of some phages. As soil pH is an important factor driving soil phage community structure (Bi et al., 2021; Lee et al., 2022), global soil acidification due to anthropogenic activities may profoundly alter viral communities. Nevertheless, we still lack knowledge of how global change factors influence the ecological functions of soil phages, with unknown consequences for soil biogeochemistry and microbiome evolution.

Soil phages can also directly and indirectly respond to global changes. Viral shunt induced by viruses drives carbon flow, increases carbon and nutrient bioavailability, and enhances surrounding microbial respiration, which may facilitate the release of CO_2 from soil to atmosphere. In particular, phage-induced mortality of autotrophs stimulates the growth of a myriad of heterotrophic bacteria that utilize soil organic matter and release CO_2 , thereby contributing to greenhouse gas emissions and exacerbating climate warming (Fig. 3). However, the net flux of CO_2 induced by soil phages has not been measured. Soil phages also

Fig. 3 Examples of the responses of soil phages to climate change and potential consequences. (A) Phage-induced mortality of soil autotrophs may stimulate the growth of heterotrophic bacteria that utilize soil organic matter and release CO_2 , thereby exacerbating greenhouse gas emissions. (B) Soil phages can also modulate soil organic matter degradation and CH_4 oxidation via expressing related AMGs, which influence the CO_2 and CH_4 emissions from soil to atmosphere.

indirectly mediate microbial metabolic response to global warming and enhance host adaption to extreme environmental conditions. For example, phage-contained AMGs related to soil organic cycling can help hosts to mineralize soil organic matter, while AMGs involved in CH₄ oxidation can decrease CH₄ flux from soil to atmosphere, indicating the dichotomous role of phages in regulating greenhouse gas emissions and influencing global warming. Moreover, viral abundances might be a significant predictor of CH₄ dynamics in some soil habitats. The $\delta^{13}\text{C}$ of porewater CH₄ in thawing permafrost soil was significantly related to the abundance of phages of methanogens and methanotrophs, rather than the single index of abiotic factors or methanogen and methanotroph abundances. At present, how phages mediate soil microbial responses to warming at different trophic levels and whether soil phages mitigate or exacerbate climate change are poorly understood. Future studies are required to incorporate phage feedbacks and contribution to global biogeochemical models, which will enable a comprehensive understanding and prediction of soil microbial responses to global changes.

Conclusions and outlook

Our knowledge of the community diversity and ecological roles of soil phages and their interactions with hosts has been advanced in recent decades, due to the rapid development in sequencing technologies, molecular-omics, SIP techniques, and new bioinformatic tools. In this chapter, we describe several important aspects of viral potential functions in soil ecosystems, including the contribution of soil phages to global biogeochemical element cycling and their potential application in regulating plant growth and health. Some critical and specific questions remain to be addressed in the study of soil viruses, including (i) how phage lifestyles (lytic, lysogeny or chronic) impact soil microbial communities and how the shift in life strategies of phages changes their ecological roles in soil ecosystems; (ii) how to reduce biases in laboratory experiments and bioinformatic analysis to comprehensively illustrate the virosphere; (iii) how to measure quantitatively the proportion and biomass of hosts undergoing phage lysis in the soil environment; and (iv) to what extent phages improve plant nutrition and protect plants from bacterial pathogen infection and how they can be used in future agricultural production and application. In addition, global change is increasingly impacting terrestrial ecosystems and changing soil microbial communities and functions, but their influences on phage diversity and functions are largely unknown yet deserved exploration. Collectively, we envision those proposed studies will unlock viral roles in various soil ecosystems and incorporate them into global biogeochemical configurations.

Abstract

Since the discovery of the Archaea as the third domain of life along with prokaryotes and eukaryotes, much has changed in terms of understanding their ecology and distribution. New molecular methodologies have revealed the wide distribution of Archaea in soils and their crucial roles in global carbon and nitrogen cycles, including influencing greenhouse gas emissions. This chapter examines the taxonomy and ecology of soil archaea, as well as some aspects of their biotechnological potential.

Glossary

Ammonia oxidation A fundamental core process in the global biogeochemical nitrogen cycle. Oxidation of ammonia (NH_3) to nitrite (NO_2^-) is the first and rate-limiting step in nitrification.

***amoA* gene** a gene that encodes subunit A of the enzyme ammonia monooxygenase (AMO), responsible for autotrophic ammonia oxidation. *amoA* has become a widely used functional and phylogenetic marker gene for bacterial and archaeal ammonia oxidizers.

Lithoautotrophs organisms which derive energy from reactions of reduced compounds of mineral (inorganic) origin.

***mcrA* gene** a gene that encodes methyl-coenzyme M reductase (MCR), that catalyzes the final methane-forming step of methanogenesis in methanogens, and the initial methane activation step in the anaerobic oxidation of methane (AOM) in anaerobic methanotrophic archaea (ANME).

Methanogenesis an anaerobic respiration exclusive to archaea that generates methane as the final product of metabolism.

Key points

- Archaea play crucial roles in global carbon and nitrogen cycles, including influencing greenhouse gas emissions
- Archaea are ubiquitous in soils and are often one of the dominant phyla in the soil microbial community
- A single gram of soil can harbor tens or hundreds of millions of archaeal cells
- Methanogenesis is a unique terminal energy-yielding process exclusive to methanogenic archaea
- Ammonia-oxidizing archaea are the major drivers of nitrification in many soils

Introduction

Since the discovery of the Archaea as the third domain of life along with prokaryotes and eukaryotes (Woese et al., 1990), much has changed in terms of understanding their ecology and distribution. Archaea were initially considered to be restricted to environments with extreme conditions such as high levels of salinity and high temperature, and environments in which they evolved to metabolize organics, such as methane, and nitrogen. However, new molecular methodologies have revealed the presence of

Archaea in a wide variety of habitats including oceans, sediments, and soils. Based on cell counts and molecular studies, Archaea typically account for 10^7 – 10^8 cells per gram of soil and 1–15% of the soil prokaryotes (Bates et al., 2011; Semenov et al., 2016, 2018).

Archaea have evolved a variety of energy metabolisms using organic or inorganic electron donors and acceptors (including fixing carbon from inorganic sources) and thus play crucial roles in global carbon and nitrogen cycles, including influencing greenhouse gas emissions (Offre et al., 2013). For example, methanogenesis and anaerobic methane oxidation are important steps in the carbon cycle that are performed by anaerobic Archaea (Liu and Whitman, 2008; Shen et al., 2019). Although both Archaea and Bacteria contribute to the globally important process of aerobic ammonia oxidation, the wide distribution of ammonia-oxidizing Archaea in virtually all investigated aerobic soils indicates a prominent role for these organisms (Leininger et al., 2006; Alves et al., 2018).

Archaeal communities and their potential roles in soil are affected by many edaphic and environmental factors. pH, carbon and nitrogen contents, vegetation, and depth may all result in changes in the abundance and composition of archaeal communities in a soil environment (Tripathi et al., 2013; Stempfhuber et al., 2015). The adaptations of archaea to energy stress provide a competitive advantage compared to bacteria. Archaea can survive under extreme salinity and pH, in which bacteria and eukaryotes cannot grow. They also have advantages when faced with energy limitation, including limited substrate supply, such as for nitrification, and minimal free-energy yields from catabolism, such as for methanogenesis and anaerobic methane oxidation (Valentine, 2007).

The archaeal cell

Archaeal cells display a wide variety of morphological types. Some, similar to species of the bacterial domain, are strictly rod-shaped or spherical. Others are disks, spirals, or filaments, or exhibit amebal irregularity, with variable protuberances. Still others have a mineral-like geometry, with shapes similar to cubes or triangles. Other irregular cells are bumpy spheres (e.g., *Thermococcus*) or are vaguely rod-shaped, but of highly variable diameter (e.g., *Pyrodictum*).

Archaeal cells possess many characteristics similar to those of the Bacteria and Eukarya, and others that are unique to the archaeal domain (Table 1). With rare exceptions, Archaea contain a cell wall that, like the cell wall of bacteria, functions to prevent osmotic lysis and to define cell shape. The ability of Archaea to adapt to extreme environments is assisted by the possession of unique cell wall types, which vary from those containing molecules composed of pseudopeptidoglycan, closely resembling bacterial peptidoglycan, to cell walls completely lacking a polysaccharide component. A common wall type is a paracrystalline surface layer (S-layer), consisting of protein or glycoprotein, generally of hexagonal symmetry. Although S-layers are common to all groups of Archaea, the biochemical makeup of S-layers among species is very diverse and, in some cases, this layer is too supple to contribute to the stability of the cell. In these cases, the function of the S-layer is unknown, but it has been proposed that the space between the cytoplasmic membrane and the outer surface of the S-layer may fulfill the role of a periplasmic space reminiscent of Gram-negative bacteria.

Archaeal RNA polymerases are complex, consisting of up to 14 subunits (compared with 4 in the bacterium *Escherichia coli*). Like Bacteria, Archaea possess a single RNA polymerase, but the archaeal RNA polymerase resembles those of eukaryotes in multisubunit complexity and sequence homology. In addition, archaeal RNA polymerases are unable to initiate transcription *in vitro*, a feature also seen in eukaryotes where general transcription factors are required for initiation.

Table 1 Some cellular features of the Archaea.

Feature of cell	Most similar to domain
Morphology	Some unique
Cell wall with pseudopeptidoglycan	Resembles bacteria
Genome consisting of single circular piece of DNA	Bacteria
DNA polymerase, DNA helicase, DNA ligase	Bacteria
Protein trafficking for sugars and inorganic ions	Bacteria
Multisubunit RNA polymerase	Eukarya
Ether-linked lipids	Unique
Promoter site for transcription	Eukarya
Lack of nuclear membrane	Eukarya
Flagellar composition and assembly	Unique
Chaperonin heat-shock proteins	Bacteria

Fig. 1 Phylogenetic tree of life.

Taxonomy and ecology

Archaea are subdivided into four superphyla: (1) Diapherotrites, Parvarchaeota, Aenigmarchaeota, Nanoarchaeota, and Nanoarchaeota (DPANN); (2) Thaumarchaeota, Aigarchaeota, Crenarchaeota, and Korarchaeota (TACK); (3) Euryarchaeota; and (4) the newly discovered Asgardarchaeota (Zaremba-Niedzwiedzka et al., 2017) (Fig. 1). Thaumarchaeota and Euryarchaeota are the two most common and abundant phyla in soils. Cultivated archaea can be divided into several broad physiological (halophiles, thermophiles, and acidophiles) or metabolic (nitrifiers, methanogens, and anaerobic methane oxidizers) groups. In further subsections, the two most important ecological groups of soil archaea will be considered—methanogens (Euryarchaeota) and nitrifiers (Thaumarchaeota).

Methanogens

Methanogens are a group of phylogenetically cohesive microbes from the domain Archaea that are responsible for the production of methane (CH_4), the second most important greenhouse gas with a global warming potential 25 times greater than that of CO_2 (Bridgham et al., 2013). Methanogenesis is a unique terminal energy-yielding process exclusive to methanogenic archaea. Methanogens can grow by reducing one-carbon compounds (CO_2 , CO, methanol, methylamines, and methyl sulfides) or acetate to CH_4 through one of several methanogenesis pathways (Table 2). Regardless of the substrate used, a methyl-coenzyme M molecule is ultimately reduced to methane by the methyl-coenzyme M reductase enzyme (MCR). Methanogens are distinguished from bacteria and other archaea that may produce methane as a byproduct of metabolism by their obligate need to synthesize methane to conserve energy using the Wolfe Cycle (Buan, 2018).

Table 2 Reactions for methanogenesis by methanogenic archaea.

Substrates		Products
1. CO_2-type		
$4\text{H}_2 + \text{CO}_2$	→	$\text{CH}_4 + 2\text{H}_2\text{O}$
$4\text{H}_2 + \text{HCO}_3^- + \text{H}^+$	→	$\text{CH}_4 + 3\text{H}_2\text{O}$
$4 \text{Formate} + 4\text{H}^+$	→	$\text{CH}_4 + 3\text{CO}_2 + 2\text{H}_2\text{O}$
$4 (2\text{-Propanol}) + \text{CO}_2$	→	$\text{CH}_4 + 4 \text{acetone} + 2\text{H}_2\text{O}$
$4 \text{CO} + 2\text{H}_2\text{O}$	→	$\text{CH}_4 + 3\text{CO}_2$
2. Methylated C1 compounds and ethanol		
$2 \text{Ethanol} + \text{CO}_2$	→	$\text{CH}_4 + 2 \text{acetate} + 2\text{H}^+$
4Methanol	→	$3\text{CH}_4 + \text{CO}_2 + 2\text{H}_2\text{O}$
4Methanol	→	$3\text{CH}_4 + \text{HCO}_3^- + \text{H}^+ + \text{H}_2\text{O}$
$4 \text{Methylamine} + 2\text{H}_2\text{O}$	→	$3\text{CH}_4 + \text{CO}_2 + 4\text{NH}_4^+$
$\text{Methanol} + \text{H}_2$	→	$\text{CH}_4 + \text{H}_2\text{O}$
3. Acetate		
$\text{Acetate} + \text{H}^+$	→	$\text{CH}_4 + \text{CO}_2$
$\text{Acetate} + \text{H}_2\text{O}$	→	$\text{CH}_4 + \text{HCO}_3^-$

All methanogens characterized so far belong to the Euryarchaeota. Currently, there are seven orders of methanogens recognized based on *mcrA* and ribosomal gene phylogeny (Adam et al., 2017). Five of the methanogen orders (*Methanopyrales*, *Methanococcales*, *Methanobacteriales*, *Methanomicrobiales*, and *Methanocellales*) so far only contain hydrogenotrophic methanogens, while the *Methanomassiliicoccales* order is defined as having obligate methyl-respiring methylotrophic methanogens. The *Methanosarcinales* have many members capable of more than one methanogenesis pathway, as well as obligate hydrogenotrophic or obligate acetoclastic members.

Methanogenesis is strongly dependent on the soil water regime and organic carbon and total nitrogen contents. Low levels of soil moisture reduce the abundance of methanogens and the rate of methanogenesis (Timonen and Bomberg, 2009; Semenov et al., 2019). In contrast, waterlogging favors the development of methanogens, which makes them an important part of microbial communities of peat, gleyic, and rice paddy soils (Kharitonov et al., 2021). Temperature also affects the diversity and abundance of soil methanogenic archaea. CH₄ emissions markedly increase with rising temperatures and are linked to the transcriptional activities of methanogens (Yvon-Durocher et al., 2014).

Ammonia oxidizers

Until recently, it was assumed that only lithotrophic bacteria and partly heterotrophic microorganisms were involved in nitrification. The discovery that lithoautotrophic archaea, thriving in oxic and moderate habitats, could oxidize NH₃ to NO₂ was unexpected. Further molecular investigations have confirmed their widespread occurrence in terrestrial ecosystems and their potential roles in nitrification, one of the most important processes in the nitrogen cycle (Leininger et al., 2006). Phylogenetic analyses based on ribosomal-proteins, other core genes, and comparative genomics strongly suggested that these mesophilic archaea should be assigned to a novel archaea phylum, Thaumarchaeota (Brochier-Armanet et al., 2008; Pester et al., 2011). After this, many more non-thermophilic Group 1.1a and 1.1b Thaumarchaeota have been isolated in pure cultures and sequenced, such as the Group 1.1a *Nitrosopumilus maritimus*, *Candidatus Nitrosopumilus salaria*, *Candidatus Nitrosopumilus sediminis* and *Candidatus Nitrosopumilus koreensis*, the Group 1.1a-associated *Nitrosotalea devanattera*, and the Group 1.1b *Nitrososphaera viennensis*, *Nitrososphaera gargensis*, and *Nitrososphaera evergladensis* (Bomberg, 2016). No representative of the Group 1.1c has yet been obtained in pure culture. The 1.1c group has been found in acidic boreal forest soils, deep peats, boreal fens, shallow peat from elevated oligotrophic subarctic bogs, and tropical peat swamp forest soils (Bomberg, 2016).

Thaumarchaeota are ubiquitous in soil and are often one of the dominant phyla in the soil microbial community (Alves et al., 2018). For example, the relative abundance of Thaumarchaeota can reach up to 20–28% in chernozem (Semenov et al., 2018) or 15–20% in phaeozem (Semenov et al., 2021). Most soil Thaumarchaeota are represented by the *Nitrososphaeria* class, which are ammonium-oxidizing archaea (AOA). The diversity and ecology of AOA have been intensively studied, often in relation to that of ammonia-oxidizing bacteria (AOB), and has relied mainly on analysis of *amoA* genes, which encode subunit A of the key metabolic enzyme ammonia monooxygenase (AMO) (Alves et al., 2018). Consequently, *amoA* became the second most frequently sequenced marker gene in microbial ecology after the 16S ribosomal RNA (rRNA) gene. Analysis of the archaeal *amoA* gene provided strong evidence that pH is a key factor driving ecology and niche specialization of AOA (Nicol et al., 2008; Gubry-Rangin et al., 2011; Pester et al., 2011; Stempfhuber et al., 2015). The C:N ratio, total organic carbon and total nitrogen contents, water content, temperature and oxygen concentration are all environmental factors affecting AOA communities (Bates et al., 2011; Alves et al., 2018).

Since the abundance of archaeal *amoA* genes often exceeds that of bacterial *amoA* genes (Leininger et al., 2006), AOA are thought to be major drivers of nitrification in many soils. This is particularly evident in acidic soils where the low pH values could drive the conversion from ammonia to ammonium, decreasing substrate availability that might selectively favor AOA over AOB as the dominating ammonia-oxidizers (Zhang et al., 2012). There is also evidence that differences in affinity for ammonia may lead to differential growth of AOA and AOB, contributing to niche separation. The growth of AOB has been linked to nitrification activity following amendment with high levels of ammonium, while the growth and nitrification activity of AOA is associated with supply of ammonia at small concentration through mineralization of organic matter (Verhamme et al., 2011).

Biotechnological potential of archaea

Biotechnologically useful enzymes represent the main focus of industrial interest in the Archaea, as a result of the abilities of these microbes to function at the temperature, salinity, and pH limits of life. Heat-tolerant enzymes are currently the most investigated of all extremoenzymes because, for many reasons, performing biotechnologically related processes at higher temperatures is often advantageous. In chemical reactions involving organic solvents, decreased viscosity and increased diffusion at elevated temperatures result in higher reaction rates. In addition, performing reactions at higher temperatures reduces the possibility of complications resulting from contamination. One thermophilic compound of particular interest is DNA polymerase, an enzyme that is responsible for the elongation of the primer strand of a growing DNA molecule and is thus central to the polymerase chain reaction for DNA amplification. DNA polymerases from various hyperthermoarchaea (including *Pwo* from *Pyrococcus woesei* and *Pfu* from *P. furiosus*) are showing biotechnological promise, based on their stringent proofreading abilities and suitability for the amplification of longer DNA fragments. These hyperthermophilic DNA polymerases possess error rates that are 5- to 10-fold less than that of the widely used thermobacterial *Taq* polymerase from *Thermus aquaticus*.

Applied uses exist or have been proposed for a variety of other archaeally derived materials. The extremely stable lipids of archaeal membranes may represent a novel drug delivery system because of their enhanced stability under temperature extremes. Archaeal components such as the S-layer glycoprotein have drawn interest for their use as possible vaccine carriers and other nanotechnological potentials, and it has been shown that much stronger immune responses in mice are shown to protein antigens encapsulated in archaeosomes than in conventional liposomes. A thermostable ligase for the ligase chain reaction (an amplification method that involves the ligation of two sets of adjacent oligonucleotides) would be of obvious benefit because the ligation must be carried out near the melting temperature of the DNA, and the ligase enzymes must be stable during the dissociation step that follows. Currently, a ligase from *T. aquaticus* is used, but a more stable equivalent may be available from hyperthermophilic Archaea. Haloarchaeal polymers have been considered as raw materials for biodegradable plastics. Hydrolases from hyperthermophiles could be used in the food-processing industry to hydrolyze fats at high temperatures, reducing bacterial contamination problems. Addition of polymer-hydrolyzing extremoenzymes such as beta-glycanases from psychrophiles to detergents would allow for efficient washing in cold water. The food industry could exploit pectinases that act at lower temperatures in the processing of fruit juices or cheeses.

Harnessing methanogens is useful to produce methane from renewable carbon feedstock. Anaerobic digestion of waste to produce biogas is a highly efficient process. Biogas comprises 30–90% methane and can be combusted to generate electricity or refined and compressed to power transportation. Methanogens have also been used to reduce the biological oxygen demand of agricultural or municipal wastewater while simultaneously producing renewable methane that can be captured from anaerobic digesters and used as fuel (Buan, 2018).

Summary

Over the past 15 years, information on the isolation, characterization, description, and applications of soil Archaea has expanded dramatically. Every few years there is news about the discovery of another archaeal phylum. It is now recognized that archaea are abundant in soil and they play important roles in global biogeochemical cycles. Methanogens and sulfate-dependent anaerobic methane-oxidizers belonging to the Euryarchaeota phylum are essential for global methane cycling under anaerobic conditions, while Thaumarchaeota are the major drivers of the aerobic oxidation of ammonia in soil. Nevertheless, the taxonomy and ecology of soil archaea remain poorly understood. Soil metagenomic surveys, coupled with efforts to cultivate these microbes, should greatly expand our knowledge of soil archaea in the future.

Abstract

Bacteria are the most abundant organisms in soil. Despite small size and relative simplicity of prokaryotic cells, bacteria are the key players in soil processes, participating in biogeochemical cycles and maintaining soil health. The ability of bacteria to thrive in soil is due to their unequalled metabolic versatility and phenotypic plasticity, which allow them to colonize different soil habitats. This chapter examines the phylogenetic and physiological diversity of soil bacteria, as well as some aspects of their survival and functioning in soils.

Glossary

16S rRNA gene A gene that encodes the RNA component of the smaller subunit of the bacterial ribosome, responsible for converting genetic messages to functional cell components via the translation of mRNA to proteins. 16S rRNA is highly conserved in the evolutionary process of bacteria, permitting the detection of relatedness among very distant bacterial species.

Horizontal gene transfer The movement of genetic material between unicellular and/or multicellular organisms other than by reproduction.

Metabarcoding The large-scale taxonomic identification of complex environmental samples via analysis of DNA sequences for short regions of one or a few genes called DNA barcodes.

Metagenomics The direct genetic analysis of collective genomes contained within an environmental sample via whole-genome DNA sequencing.

Rhizosphere A narrow zone of soil adjacent to the roots of living plants that is directly influenced by root exudates.

Key points

- Soil bacteria carry out key ecosystem services, including cycling of carbon and other nutrients and sustaining plant growth
- A single gram of soil can harbor billions bacterial cells and tens of thousands bacterial species
- Soil bacteria can be categorized on the basis of their ecological strategies and used to predict soil functions
- Microscale spatial patterns regulate bacterial activity in soil
- Cooperative and coordinated behaviors are required for the development of bacterial community

Introduction

Bacteria are the most abundant organisms in soil, second only to fungi in their contribution to global soil microbial biomass (7 Gt C) (Bar-On et al., 2018). The majority of soil bacteria have a diameter of 0.5–1.0 μm . There are also many ultramicrobacteria (also known as “nanobacteria”) in soil, which are less than 0.2 μm in diameter (Lysak et al., 2010). Therefore, the average mass of a soil bacterial cell is only 2×10^{-14} g dry weight (or 10^{-14} g C) (Polyanskaya et al., 2017). Despite small size and relative simplicity of prokaryotic cells, bacteria are the key players in soil processes, participating in biogeochemical cycles and maintaining soil health (Crowther et al., 2019; van Bruggen et al., 2019). Soil bacteria can regulate nutrient availability, aggregate stability, C sequestration, pollutant degradation, plant health and plant growth promotion (Fierer, 2017). They are also involved in the cycling of trace gases, such as nitrous oxide (N_2O), nitric oxide (NO), carbon monoxide (CO), hydrogen (H_2) and reduced sulfur species, which affect the chemistry of the atmosphere and, thus, indirectly also affect the radiation balance of Earth.

The species concept for bacteria is still obscure. It has been proposed that the species in prokaryotes correspond roughly to the genera of eukaryotic organisms, and that prokaryotic ecotypes correspond to eukaryotic species. The most accepted species definition, the phylo-phenetic species, is defined as a monophyletically and genomically coherent cluster of individual organisms that show a high degree of overall similarity in many independent characteristics and is diagnosable by a discriminative phenotypic property (Bergey, 2001; Torsvik and Øvreas, 2006). The 97% 16S rRNA similarity level has been chosen as a threshold criterion for defining bacterial species. Its use for the description of bacterial diversity is, however, limited since strains of the same bacterial species, namely organisms whose indicator 16S rRNA sequences are >97% similar, typically only share some genes, while other genes are strain-specific and unique (Fernández et al., 2019). The traditional species concept as isolated clusters of genetically compatible isolates may be shifted to a cohesive speciation network in which such clusters are interconnected by genetic processes.

The most important issues related to soil bacteria are their phylogenetic and physiological diversity, patterns of spatial distribution and metabolic activities at the scale of the microbe, as well as life strategies and survival of bacteria in the soil environment. The ability of bacteria to thrive in soil is due, in part, to their unequaled metabolic versatility and phenotypic plasticity, which allow them to colonize the vastly different habitats that make up soils. Bacteria, probably more than any other type of organism, can quickly adapt to fluctuations in environmental conditions, both in physiological and genetic terms. Life in soil has clearly driven bacteria to fine-tune their genetic systems and genomes over evolutionary time allowing them to cope directly with the local conditions offered by the soil environment (Standing and Killham, 2006).

Bacterial phylogenetic and physiological diversity

Soil is the most complex environment with greatest microbial diversity (Walters and Martiny, 2020). A single gram of soil can harbor up to 10^{10} – 10^{11} bacterial cells and an estimated diversity of tens of thousands of species (Wagg et al., 2014). Bacteria account for up to 99% of the genes in the soil metagenome (Semenov, 2019). Until recently, it was impossible to detect the vast majority of bacterial diversity, since most soil microorganisms (95–99%) do not grow readily under standard laboratory conditions. However, direct extraction and characterization of microbial community DNA through PCR amplicon surveys (metabarcoding) and metagenomics has revolutionized our ability to characterize microbial diversity by enabling the investigation of community composition at a much greater phylogenetic resolution than ever before (Nesme et al., 2016; Semenov, 2019). Metagenomic analysis of nucleic acids provides direct access to the genomes of the “uncultivated majority” (Nesme et al., 2016). According to 16S rRNA gene amplicon sequencing, all soil bacterial communities are dominated by Acidobacteria, Actinobacteria, Bacteroidetes, Proteobacteria, and Verrucomicrobia (Fierer et al., 2012). Additional phyla including Chloroflexi, Cyanobacteria, Firmicutes, and Gemmatimonadetes are also found in nearly all soils (Fierer et al., 2012). In contrast to the other dominant bacterial taxa, most Verrucomicrobia have not been yet isolated in pure culture. However, this phylum is one of the main dominants in prokaryotic communities; their proportion typically varies from 5 to 15–25% of prokaryotic sequences (Semenov et al., 2018). Despite such high abundance, we lack a predictive understanding of the ecological attributes of most soil individual verrucomicrobial taxa, with their environmental preferences, traits, and metabolic capabilities remaining largely unknown.

From an ecological point of view, information regarding the metabolic functions of soil bacterial communities is certainly the most relevant (Baldrian, 2019). Currently, one of the most relevant issues in soil microbial ecology is the conversion of the soil bacterial taxonomic profile obtained by metabarcoding or metagenomics into a functional profile (Alteio et al., 2021; Blagodatskaya et al., 2021). The functional diversity of a bacterial community has been defined as the occurrence and distribution of physiological and metabolic traits among member of that community (Torsvik and Øvreas, 2006; Malik et al., 2020). Functional diversity can be expressed as the number of different functional groups (guilds) present. For instance, soil bacteria can be described by their physiological and ecological properties (Table 1).

Adaptive loss of function or genome streamlining, convergent evolution and horizontal gene transfer all erode the phylogenetic signal of many traits (Louca et al., 2018). Horizontal gene transfer also leads to low genetic linkage of traits within genomes and hence to re-assortment of traits between genomes. Some *Escherichia coli* strains, for example, overlap by less than 40% in their protein-coding genes. The phylogenetic scale on which functions are conserved varies strongly between functions, and even for single functions phylogenetic conservatism can vary between clades (Fernández et al., 2019). As a result, the contrast between stable functional composition and variable taxonomic composition seen in the aforementioned studies reflects a weak association

Table 1 Examples of physiological and ecologic classifications of soil bacteria.

Category	Classification	Description
Nutritional	Heterotroph	Able to use organic compounds as energy and carbon source
	Phototroph	Able to use light as its energy source
	Autotroph	Able to use carbon dioxide as a sole carbon source
	Chemolithotroph	Able to use an inorganic substrate as an electron donor
Functional	Saprophyte	Degrades nonliving organic material
	Nitrifiers	Oxidation of ammonia to nitrite and nitrate
	Denitrifiers	Reduction of nitrate to dinitrogen gas
	Nitrogen-fixers	Reduction of dinitrogen gas to ammonia
	Sulfate-reducers	Reduction of sulfate to hydrogen sulfide
	Sulfate-oxidizers	Oxidation of elemental sulfur to sulfate
	Decomposers	Breakdown of complex compounds into simpler compounds
Interactions	Commensalism	One organism benefits while the other is neither harmed nor benefits
	Parasitism	One organism benefits while the other is harmed
	Mutualism	Both organisms benefit

between many functions and bacterial phylogeny (Baldrian, 2019; Alteio et al., 2021). Quantification of microbial diversity involved in various metabolic functions also revealed that communities typically exhibit high ‘functional redundancy’ with respect to a multitude of functions, in the sense that each metabolic function can be performed by multiple coexisting, taxonomically distinct organisms (Louca et al., 2018).

A multitude of biotic and abiotic factors affects the structural and functional diversity of soil bacteria. Soil pH is considered as the best predictor of bacterial community composition (Delgado-Baquerizo et al., 2018). Also, important factors that have notable influences on the structure of soil bacterial communities are nitrogen availability, soil organic carbon content, temperature, moisture, and redox status (Fierer, 2017).

The microbe as the scale of study

It is important not to neglect the element of scale as we try to understand bacterial behavior and processes (Blagodatskaya et al., 2021; Hugoni et al., 2021). While macro- and mesoscale distributions of microbes indicate the average abundance of microorganisms through volumes of soil, it is the patterns of distribution and metabolic activities at the scale of the microbe (the microscale) that will control many microbial behaviors (Blagodatskaya et al., 2021; Raynaud and Nunan, 2014). Studies on microbial systems (whether they focus on microbial activity or diversity) are generally carried out at scales many orders of magnitude larger than those at which microorganisms interact with other organisms or with their surrounding environment (Baldrian, 2019). From the perspective of a bacterium, a volume of soil or a root several centimeters away can represent the distance of tens kilometers. The 1–10 µm scale will be of greater significance for growth and activity of bacteria than bulk soil properties.

Solid aggregates separate the soil into many fully or partially isolated microniches with contrasting conditions (Standing and Killham, 2006). Bacteria inhabit these niches in accordance with their needs for nutrition and survival, resulting in an uneven distribution of the microbiome inside soil aggregates (Fig. 1). The high heterogeneity of bacterial communities is also due to the complexity of the soil pore system. For example, bacteria are able to enter and colonize small soil pores, potentially protecting them from predation. Moreover, micropores and biofilms on macropore walls often contain higher concentrations of organic substances that can be used by microorganisms as substrates.

Microscale spatial patterns may have a regulatory effect on bacterial activity, as a result of the diffusive delivery of substrate to, and the dispersion of product from bacterial cells, which may have rate-limiting or stimulatory effects on microbially mediated processes (Raynaud and Nunan, 2014). Furthermore, bacteria can release chemical signals that modulate bacterial functions once a critical concentration of chemical is reached (known as quorum-sensing). Spatial separation controls horizontal gene transfer in bacterial populations.

Bacterial life strategies and survival

Heterotrophic bacterial taxa can be divided into broad categories on the basis of shared life strategies and survival (Fierer, 2017; Malik et al., 2020; Blagodatskaya et al., 2021). For instance, soil bacterial taxa could be grouped by growth and efficiency into r- and K-strategists. The r-selected strategists have short life expectancy and large reproductive effort, whereas K-selected strategists have long life expectancy and invest a smaller proportion of energy and resources into reproduction. The copiotroph-oligotroph continuum is proposed as analogous to the r- and K-selection theory and is based mainly on microbial substrate preferences and trophic strategy. Another option is to modify a trait-based competitor–stress tolerator–ruderal (C-S-R) concept and adopt it to

Fig. 1 Microscale distribution of soil bacteria.

categorize the broad spectrum of soil bacterial lifestyles (Fierer, 2017) (Table 2). ‘Stress-tolerant’ taxa can persist under low-resource or suboptimal abiotic conditions. ‘Competitor’ taxa outcompete other soil microbial taxa for space or resources. ‘Ruderal’ taxa grow rapidly and exploit unoccupied niches generated as a result of biotic or abiotic disturbances.

The C-S-R strategies do not fully reflect microbial systems due to the reliance of heterotrophic microorganisms on an external source of carbon and energy that drive differential cellular allocation and lead to tradeoffs in traits. This makes the quantity and quality of resources in the surrounding environment a key factor in influencing species distribution. In addition, the way microbes respond to disturbance and stress may not be entirely distinguishable. To overcome these limitations, a new Y-A-S (yield-acquisition-stress tolerance) life strategy theory for soil bacteria was recently proposed (Malik et al., 2020) (Table 3). High yield (Y) strategists maximize the fraction of resource uptake that is allocated to biosynthetic processes by investing in central metabolism and associated assimilatory pathways such as amino acid, nucleotide, and fatty acid synthesis to build cellular components using these precursor compounds. The absence of resource limitation and stress are expected to favor the high yield strategy. The resource acquisition (A) strategy prevails in low-resource conditions where bacteria would be under selection to increase resource capture at the expense of growth yield. Microbes exposed to suboptimal abiotic conditions would possess traits linked to stress tolerance (S) at the expense of other traits (Malik et al., 2020). Recent developments in molecular approaches have provided potential for microbial trait differentiation based on information regarding genome size, number of ribosomal gene copies per genome, and quantification of functional marker genes or their transcripts by -omics approaches (Li et al., 2021).

Table 2 Examples of physiological and ecologic classifications of soil bacteria (based on Fierer, 2017).

Classification	Description	Examples
Stress-tolerators	Auxotrophic	Acidobacteria
	Slow growth	Chloroflexi
	Few rRNA operon copies	Verrucomicrobia
	High substrate affinity	
	Production of extracellular polymeric substances (EPS)	
Competitors	Larger genomes	Many Actinobacteria (e.g. <i>Streptomyces</i>)
	Antibiotic production	Many α - and γ -Proteobacteria (e.g. <i>Pseudomonas</i>)
	Filamentous growth	
	High catabolic diversity	
	Siderophore production	
Ruderal	Rapid growth	Many Firmicutes (e.g. <i>Bacilli</i>)
	Multiple rRNA operon copies	Many β -Proteobacteria (e.g. <i>Burkholderia</i>)
	Low catabolic diversity	Many Bacteroidetes (e.g. <i>Flavobacterium</i>)
	Spore formation	
	Low C/N ratio	

Table 3 Y-A-S life history strategies and underlying traits of soil bacteria (based on Malik et al., 2020).

<i>Classification</i>	<i>Conditions</i>	<i>Description</i>
Growth yield (Y)	Resource abundance Ambient	Growth per unit resource
Resource acquisition (A)	Resource limitation Ambient	Degradation of complex substrates Motility: resource discovery Uptake of simple substrates
Stress tolerance (S)	Resource limitation Stressed	Biomolecular damage repair Osmolyte production Extracellular polymeric substances (EPS) synthesis Maintenance of cellular integrity

Avoidance

To avoid a stress, bacteria need to actively reposition themselves toward a more hospitable site. Avoidance can also happen passively when bacteria are physically repositioned in the soil profile by root movement or through some other physical disturbance, but this is not an effective strategy for surviving stressful times. If bacteria grow or survive at particular sites in soils, then the ability to move to such sites is an important arsenal in their survival strategies. Bacterial motility is likely to play a role in positioning them in a niche that is abundant in desirable nutrients, low in toxic or undesirable compounds, or provides protective sites. Although flagellar motility requires a sufficiently thick water film, which is more common in wetter soils, it is possible that twitching or surface motility may play a role in positioning the cell in a favorable site, particularly when water films are too thin for flagellar motility, which more commonly occurs in unsaturated soils. It is uncertain over what distances could bacteria move using this form of motility, but it would be shorter than that covered by flagellar motility.

Once a bacterium reaches a favorable site, the ability to resist removal may be advantageous. The strength of the selective pressure depends on the strength of the removal pressure, such as water percolation following rain, tillage, or movement of a root through soil. Once associated with a surface, bacteria can adhere to it by specific attachment structures such as cellulose fibrils, membrane proteins, pili, or extracellular polymeric substances (EPS), such as polysaccharides. It has been hypothesized that bacteria employ specific adhesins in environments where there are strong physical forces. Due to the improbability of continuous strong shear forces in soil, bacteria probably do not use adhesion extensively, except when they occupy sites that offer some protection, or are nutrient-rich, or on roots, because root movement could provide sufficiently strong physical forces to cause their removal.

Stress tolerance

Bacteria in soil are exposed to a variety of environmental conditions that are going to affect them such as, for example, fluctuations in temperature, availability of water and nutrients, the presence of toxic environmental pollutants, or toxic metabolic wastes produced by themselves or by their neighbors. Survival in a continually changing environment requires a wide range of fast, adaptive responses, some of which do not require transcriptional activation of genes whose products facilitate coping with a given stress, since these responses take too long to complete. For example, modification of fatty acid composition in pseudomonads provides an extremely rapid response to maintain membrane fluidity when they are exposed to stresses such as desiccation or organic solvents that perturb membrane properties. Transcriptional activation of genes whose products facilitate coping with stress provides more long-term solutions. It is not feasible to review bacterial responses to every stress they will potentially encounter in soil. Here, reduced water availability is highlighted, and this is likely to be a dominant factor influencing bacteria in many soils; the mechanisms of adaptation to this stress are likely to be similar to the mechanism for adaptation cold or heat stress, two common stresses bacteria frequently experience in surface soils, since they all alter physical properties of bacterial membranes.

Water availability

If solutes are abundant in free soil-water, they could become sufficiently concentrated upon drying to stress the resident bacteria. Osmotic stress is only one component of the total water stress that a bacterium may encounter in soil as it dries. The total soil-water potential is a quantitative term reflecting water availability. It is comprised primarily of the sum of the osmotic potential, which is due to the interaction of water with solutes, and the matric potential, which is due to the interaction of water with soil constituents that increases as the soil dries. From a bacterial perspective, the primary difference between these two stresses is that with an osmotic stress bacteria are bathed in water (albeit water with diminished activity), whereas with a matric stress bacteria become desiccated by removal of water from its environment, and the availability of the water that is remaining is reduced due to its sorptive interactions with soil constituents. The stress imposed by a low matric potential has a stronger influence on a bacterial cell than an equivalent osmotic potential. This is due in part to the greater cellular dehydration that occurs under a matric than an osmotic stress. Dehydration produces DNA damage, denatures proteins, and causes membranes to become less fluid and potentially damaged. Resistance to dehydration is crucial for microbial life in soil habitats. These include various strategies to counter the life-threatening,

lipid-solidifying effects of desiccation, synthesizing solutes compatible with cellular physiology to create an intracellular water potential that is in equilibrium with the external environment, protecting and repairing DNA, and producing EPS.

Extracellular polysaccharide production

There is considerable evidence that soil bacteria are capable of producing EPS, especially polysaccharides, and increased EPS production by soil bacteria has been shown to improve soil aggregation, aggregate stability, and water retention properties. These polysaccharides are likely to have a dominant role in the ecology of these organisms, since their presence defines the environment immediately surrounding the bacteria. As such, they mediate the interactions of the bacteria with the surface, other microorganisms, and the physical and chemical environment. The EPS matrix that surrounds them can have ion-exchange capabilities, which can concentrate nutrients from dilute sources in the vicinity of the cell or provide protection from predators and shield cells from the action of lytic enzymes, antibiotics, and other inhibitory compounds. EPS production may be particularly important during desiccating conditions, because many EPS are hygroscopic and their production results in a more hydrated microenvironment in the immediate vicinity of the cell relative to the bulk environment. The greater water content in the immediate vicinity of cell membranes may reduce the physical damage to membrane properties that might occur otherwise. This is an example of how habitat modification can benefit the resident bacteria.

Many studies have revealed aggregates of bacteria in bulk soil or on root surfaces. These bacteria are closely packed and covered with an amorphous material that is presumably EPS. This association of aggregates of bacteria in a matrix is analogous to that of biofilms, which are defined as assemblages of bacteria on surfaces encased in EPS of their own making.

Competition for resources

Soil bacterial communities are characterized by high temporal dynamics which mirrors permanent fluctuations and recurrent variations in the community structure, composition or function (Zelenev et al., 2005). Temporal fluctuations of soil bacteria are governed not only by environmental conditions, but also by intra-species and inter-species interactions relationships (Zelenev et al., 2006). Bacteria of different species co-occur in soil and, if these species occupy the same microsites, the survival of any one of them depends on its ability to compete successfully for shared resources or to coexist by utilizing different resources (Zelenev et al., 2005; Zelenev et al., 2006). These resources can include the same physical site or be nutritionally based, and competition for nutrients is a driving factor in microbial ecology of bacteria in soil. Thus, a broad nutrient utilization profile would increase the potential for an organism to survive in the presence of others and the ability to utilize an abundant resource should be highly advantageous as long as other resources are not limiting. Many soil bacteria, and in particular, rhizosphere (the root surface and the region immediately surrounding a root) colonists have broad nutrient utilization profiles. Likewise, the ability of soil bacteria to tolerate prolonged nutrient deprivation would also be highly advantageous. If microbes must compete for limited resources, production of antimicrobial metabolites, such as an antibiotic, could improve their competitive ability. Many soil bacteria are capable of producing antibiotics that target dissimilar organisms or bacteriocins that target more closely related strains of the same species, and their production would conceivably provide a competitive advantage.

The rhizosphere constitutes an ecologic niche where nutrients are more readily available compared with the bulk soil. The ability to compete effectively for these nutrients is likely to be an important factor contributing to the ability of a bacterium to become a rhizosphere colonist. The deposition of organic material from the roots (rhizodeposition) enhances microbial growth, drives the structuring of microbial communities, and controls their metabolic activities in the rhizosphere (Kuzyakov and Blagodatskaya, 2015). The interactions between the plant and the surrounding bacteria in the bulk soil select for the establishment of certain populations (rhizobacteria). While rhizodeposition strongly influences the size and activity of microbial populations at the soil–plant interface, the activity of these populations in turn affects plant health and thus influences both the quantity and quality of rhizodeposition. The potential for either an exudative response to bacteria or a response by bacteria to exudation suggests a certain degree of coevolution between plants and rhizobacteria.

Cooperation among bacteria

The ability to modify a habitat may be augmented by cooperative interactions among bacteria and these interactions may occur among both homogeneous and heterogeneous populations. The occurrence of aggregated populations of bacteria in soil or in association with plant roots provides an opportunity to maximize opportunities for interactions among community members. There have been several recent descriptions illustrating sophisticated cooperation among community members, even though at times they may appear not to be cooperative attributes.

Siderophores

Although iron is abundant, the extreme insolubility of ferric hydroxide limits the amount of free iron available in aerobic soil environments since the iron exists in the form of insoluble oxides at neutral or alkaline pH soils. Many bacteria use siderophores and corresponding membrane receptors to acquire this essential nutrient (Souza et al., 2015). Siderophores, which are low-

molecular-weight molecules produced under iron-limiting conditions, bind the ferric iron (Fe^{3+}), the membrane receptor recognizes a particular siderophore–iron complex, and the iron is then transported into the cell. Any particular bacterial species or strain generally produces one or more siderophores and the corresponding membrane receptors for transporting each siderophore–iron complex into the cell. The bacterium releases the siderophore into the environment and then the siderophore needs to chelate ferric iron and diffuse back to the cell for the cell to benefit from the energy spent to synthesize the siderophore. Yet many soil bacterial species have the capacity to utilize siderophores produced by other bacterial strains or species and possibly fungi (Souza et al., 2015). This cross-feeding clearly provides advantages to community members, since there is a greater potential return on the metabolic investment of siderophore production by taking up ferric–siderophore complexes that it did not synthesize rather than depending solely on diffusion of the siderophore it produced back into the cell. This illustrates that bacterial survival may not depend solely on the efforts of the individual but also, in part, on the efforts of the community.

Quorum-sensing

Bacteria can communicate with one another using chemical signaling molecules. Specifically, they release, detect, and respond to the accumulation of molecules called autoinducers. Detection of autoinducers allows bacteria to distinguish between low and high cell population density, and to control gene expression in response to changes in cell number. In reality, this is not necessarily a function of high cell density, but is likely to be related more directly to high signal concentrations, which are likely to be achieved at lower population densities in soil due to their low water volumes that result in relatively high autoinducer concentrations. This process, termed ‘quorum-sensing,’ allows a population of bacteria to coordinately control gene expression of the entire community and allows the bacteria to behave as multicellular organisms and to reap the benefits that would be unattainable to them as individuals (Hawver et al., 2016). Many microbial behaviors are regulated by quorum-sensing, including, for example, expression of nodulation genes in the *Rhizobium*–legume symbioses, virulence traits of bacterial pathogens of plants, conjugal transfer of plasmids between bacteria, antibiotic production, and biofilm formation (Bogino et al., 2015).

Many bacteria have also developed mechanisms to interfere with bacterial quorum sensing, such as secreting enzymes that destroy autoinducers or producing autoinducer antagonists. Furthermore, some plants secrete substances that mimic or interfere with *N*-acyl-homoserine lactone autoinducer signal activities and affect population density-dependent behaviors in associated bacteria. These autoinducer signal-mimic compounds could prove to be important in determining the outcome of interactions between higher plants and a diversity of pathogenic, symbiotic, and saprophytic bacteria. Furthermore, some bacteria are capable of recognizing autoinducers produced by different bacterial species, indicating that interspecies quorum-sensing may play an important synergistic or competitive role in the dynamic behaviors of soil bacterial communities (Hawver et al., 2016).

Summary

Soil bacterial communities are surprisingly diverse and abundant; a single gram of soil can harbor billions bacterial cells and tens of thousands bacterial species. Soil bacteria carry out key ecosystem services, including cycling of carbon and other nutrients and sustaining plant growth. Recent advances in marker gene and metagenomic analyses have greatly expanded our ability to characterize the soil bacterial communities, taxonomically and functionally, and identify the factors that shape them across space and time. One of the most relevant issues in soil microbial ecology is the conversion of the data on bacterial taxonomic profile into a functional status of the soil. Although most soil microorganisms remain undescribed, we are able to categorize soil bacteria on the basis of their ecological strategies and thereby predict the soil functions.

The ability of bacteria to survive in soil with its inherent complexity and heterogeneity under conditions that are often severe is a testament to their metabolic versatility and phenotypic plasticity (adaptability). Many bacteria are able to modify their local environment, such as by producing EPS, to facilitate growth, and their increased numbers facilitate further habitat modification. Cooperative and coordinated behaviors are required for the development of bacterial community. Each individual member of the community, through its own actions, based in part on the signals it receives from other community members, initiates a spectrum of adaptive strategies that are appropriate for the particular habitat they reside in and the specific environmental challenges they are experiencing to optimize chances for survival.

Abstract

Protists are the most abundant and diverse eukaryotes that inhabit virtually all soils. They are active players in soil food webs as phototrophic algae, plant and animal parasites, and microbiome predators. As predators, protists lead to modification of their prey community composition typically promoting functions linked to (plant-)pathogen suppression. The diverse functional roles of protists are further connected to cycling of carbon, nitrogen and other nutrients such as phosphorous and silicon. Thanks to their link to plant growth and their dynamic response to environmental changes, soil protists are further suggested as bioindicators of soil and plant health.

Key points

- Protists are the most abundant and diverse eukaryotes in soils
- Soil protist can have local or global distribution
- Protists drive microbiome dynamics and soil fertility
- Protists can favor pathogen suppressive microbial communities
- Protists are valuable bioindicators to monitor soil health

Introduction

Protists are among the most abundant and diverse microorganisms. Protists are a paraphyletic group referring to all Eukaryotes except plants, animals and Fungi. Soil protists are mostly unicellular and display a size range of few micrometers to millimeters. As to be expected from their broad phylogenetic coverage, protists exhibit a huge variety of morphotypes with the classical division between amoebae, flagellates, ciliates and shell-forming (testate) types; we provide some examples of protist species from different sizes and morphotypes in Fig. 1.

In the soil context, protistologists have primarily focused their efforts on the heterotrophic, free-living protists, traditionally referred to as “protozoa.” Many heterotrophic protists are predators and feed on relatively small prey such as bacteria and yeasts by ingesting them via phagocytosis, but others graze or attack bigger organisms such as hyphal-forming fungi and other micro-eukaryotes (Geisen et al., 2018). While protist predators have recently been reported to be the most abundant functional group in many natural soil ecosystems (Oliverio et al., 2020; Xiong et al., 2021), soil protists can also be autotrophic, mixotrophic or parasitic. Soil protists thus exhibit a range of ecological functions from primary producers to decomposers, and include important predators and pathogens (Geisen et al., 2018).

As a consequence of such ecological breadth, the study of protists has been spread over different research fields that have historically been disjunct. Autotrophic protists were, for instance, typically studied by botanists, while heterotrophic protists were considered as part of zoology. In the early 2000s, a framework called the eukaryote Tree of Life (abbreviated eToL) was established to reconnect this knowledge. Five to eight so-called ‘supergroups’ were created as broad assemblages to help classify the protists. These supergroups were initially based on morphological or cell biological features (e.g., the posterior flagellum in motile cells for the Opisthokonta, the red alga-derived plastids for the Chromalveolata) and have, since then, been strongly remodeled, increasingly based on (multigene) molecular phylogenetic information and less so on distinctive biological features. The contemporary discovery of novel taxa also continues to contribute to the remodeling of these supergroups (Burki et al., 2020). We present in Fig. 2 a schematic representation of the phylogenetic tree of the eukaryotes, highlighting with brown dots common taxonomic groups found in soils.

Soil protistology has received a constant interest over the last decades with an average of 93 ± 11 publications (per 5 years) for the period between 1980 and 2010. The related research effort is further very likely to follow a steady growing curve as witnessed for the aquatic environments with an observed 20% relative increase in the number of publications (per 5 years) for marine systems from 1995 to 2020 and 30% relative increase for freshwater and aquatic systems for the period 2005–2020 (see Fig. 3 below). Indeed, the number of publications related to soil protists has more than doubled in the last 10 years (83 publications reported for the 2005–2010 period, versus 183 for 2015–2020) and include important research and reviews that especially highlight soil protist taxonomic and functional diversity. Due to their link to plant growth, the essential role of soil protists in agroecosystems is also increasingly recognized. In addition to their relation to plant growth, the dynamic response of soil protists to environmental changes has further suggested protist community composition to be indicative of soil condition (Foissner, 1999).

In this article, we aim at providing an overview of the current knowledge on soil protists. We will first present the main adaptations allowing protists to thrive in the soil ecosystem. We then present the biogeography and the ecological roles of soil protists. We further highlight some particularities of the impact of agroecosystems on soil protists and on the relation between protists and plant performance. We also present the potential to apply protists as valuable bioindicators, before concluding with a synthesis and providing perspectives of the immense potential of soil protistology.

Diversity and ecology

We here first briefly review some of the main adaptations of protists required to inhabit the soil ecosystem and provide estimations on protist abundances and diversity in soils. We present the geographical distribution and diversity patterns of terrestrial protists. We finish this section on the ecological role of soil protists as predators and parasites and how they relate to nutrient cycling.

Adaptations to the soil ecosystem

Most soil protists produce viable resistant structures usually refer to as cysts to withstand the unique set of challenges associated with life in soil. The soil is a complex matrix characterized by pores of different dimensions and connectivity. In addition, a distinct set of physicochemical variables, such as pH and moisture content, typically governs soil microbial biodiversity. Water content, especially,

Fig. 2 Schematic representation of the phylogenetic tree of eukaryotes. The brown dots indicate taxonomic groups that are particularly diverse and abundant in soils. Non-protist taxa (land plants, animals, and fungi) are highlighted in boxes. Reproduced with permission from Geisen S, Mitchell EAD, Adl S, Bonkowski M, Dunthorn M, Ekelund F, Fernández LD, Jousset A, Krashevskaya V, Singer D, Spiegel FW, Walochnik J, and Lara E (2018) Soil protists: A fertile frontier in soil biology research. *FEMS Microbiology Review* 42: 293–323. <https://doi.org/10.1093/femsre/fuy006>.

Fig. 3 Overview of studies specifically mentioning protists and the studied habitat (marine, freshwater, aquatic or soil) in the title in 5-year intervals from 1980 to 2020. The literature research has been done on web of science on the 11.04.2021 based on the keywords previously used in the study of Geisen et al. (2017).

can vary dramatically and impose an important pressure on soil protists, which are particularly sensitive to dehydration and rely on water for movement (Geisen et al., 2018). When encysting, the cells typically round up, lose water and secrete a thick wall (the exact composition of which is specific to distinct protist groups) to form a coccoid structure. The longevity of the cysts typically depends on the environmental conditions in which the cells live: cysts formed in arid environments can survive desiccation for decades, while those produced in rainforests only survive for a few weeks or months. In addition to water availability, environmental variables such as pH and salinity as well as biotic variables, such as prey abundance and activity (e.g., production of cyst-inducing compounds), can also induce encystment (Geisen et al., 2018). Cyst formation is thus valuable in a heterogeneous and dynamic environment such as the soil, where moisture content fluctuates as well as the abundance and identity of prey varies.

The physical structure of the soil, which can be described in terms of pore geometry, connectivity and hydration status, further governs the ability of soil organisms to sense and access their food or prey. This is especially true for micro-organisms such as bacteria, protists and nematodes that are bound to the given soil structure and are not able to modify it by, for example, physically creating pores (Erktan et al., 2020). Small pores typically provide valuable refuges for small bacteria against predators too big to access them, but amoeboid protists are particularly well-adapted to reach these small cavities. Amoeboid protists have a flexible body that they can extend in arm-like projections, called pseudopods, to reach such cavities and access their prey (Erktan et al., 2020). A representation of the soil structural complexity and its impact on predator-prey interactions is given in Fig. 4 below.

Abundance and diversity in soils

In terms of abundance, soil protists are generally estimated to range from a few hundred to a million individuals per gram of dry soil (Geisen et al., 2018). With an average of 1.6 gigaton of carbon (Gt C), the soil protist biomass contributes to ca 7% of the terrestrial biomass (the percentage is given after excluding plant biomass and based on the supplementary Table S23 of Bar-On et al., 2018). The protist biomass follows that of soil bacteria with 7 Gt C (32%) and fungi with 12 Gt C (55%) and exceeds that of archaea and animals. Therefore, soil protists contribute far more to the terrestrial biomass than other higher trophic organisms; about $8 \times$ more than arthropods (including all insects on the planet) and $250 \times$ more than nematodes (the most abundant animals).

Protists are estimated to be one of the most diverse eukaryotic groups in soils. In addition, soils have been recently highlighted as hotspots of protist richness compared to freshwater and marine ecosystems (Singer et al., 2021). About 21,000 protist species have been identified in soils, but this has been estimated to represent only about 2% of the true total species richness ($>1,000,000$ species; Geisen et al., 2018). Noteworthy, these numbers are more than 10 times larger than in 2005, when Foissner reported ca 1600 known terrestrial species and an estimated total richness of 3700 species in the first edition of this book. Such an increase in less than two decades is mostly explained by the development of molecular methods allowing for higher taxonomic identification possibilities.

Not all protist groups, however, contribute equally to the soil protist community with some species being relatively rare and others rather dominant. The dominant taxonomic groups in soils are Cercozoa and the Ciliophora, as they together constituted 73% of all reads obtained from 180 soils across six continents (Oliverio et al., 2020). In terms of ecological functions, the most abundant group in soils is further suggested to be formed by predators which can contribute to up to 75% of the total reads (Oliverio et al., 2020; Xiong et al., 2021). The proportion of other functional groups (i.e., phototroph and parasites) is further determined by the ecosystem type. For example, arid ecosystems tend to have relatively more autotrophs, which can even represent up to 40% of the total protist community, while tropical forests are typically characterized by higher abundance of parasites that contribute up to 38% of the total protist community (Mahé et al., 2017; Oliverio et al., 2020).

Geographical distribution and diversity patterns

Species richness is usually not randomly distributed but follows distinct diversity patterns. Such patterns are typically investigated in biogeography, i.e., the study of the distribution of biodiversity over space and time (Martiny et al., 2006). Biogeography of micro-organisms has been the focus of many studies supporting various models going from a random distribution of species to the dominant contribution of either historical events or contemporary environmental conditions (Martiny et al., 2006). The soil protists are no exception as illustrated by the debate between the 'ubiquity model' of Fenchel and Finlay (2004) and the 'moderate endemicity model' of Foissner (2008). While both models assume that most protists are cosmopolitan, Foissner (2008) argued that some species show local endemism. Local endemism is predicted for organisms with relatively high speciation rate and low dispersal potential. High speciation is usually expected for most soil protists as they have relatively short generation times that can thus foster mutations leading to speciation. The dispersal potential, however, may vary between species, as some protists are relatively large and some even lack the ability to produce long-term viable cysts (Foissner, 2008). The complete absence of an organism in a given environment cannot be proven with certainty as this could be due to under-sampling or sampling biases. Yet, there are some well-known examples of flagship species that are easy to observe and study, and appear to have a restricted biogeographic distribution. The relatively large (130–210 μm) testate amoeba *Apodera vas* has been recognized as such a flagship species: it has only been found in South and Central America and Sub-Saharan Africa, but is lacking in North America and Eurasia. Other clear examples of local endemism are found within parasitic protists, such as some *Phytophthora* species, which distribution is directly dependent on the presence of their host. *Phytophthora agathidicida* is, for instance, only found in New Zealand, where its host, the kauri tree (*Agathis australis*), is endemic. Hence, with the enormous taxonomic breadth and corresponding life strategies

Fig. 4 Representation of the soil structural complexity and its impact on predator-prey interactions for organisms of different sizes. The ability of amoebae to reach prey in small pores is highlighted in panel A, while panel C represents a tri-partite interaction providing access to bacterial prey for nematodes through smaller sized protists (in this case a ciliate) functioning as intermediate predators. Reproduced with permission from Erktan A, Or D, and Scheu S (2020) The physical structure of soil: Determinant and consequence of trophic interactions. *Soil Biology and Biochemistry* 148: 107876. <https://doi.org/10.1016/j.soilbio.2020.107876>.

understood behind the term ‘protist’, there is a clear support for a ‘moderate endemicity model’ where some taxa are globally distributed (i.e., cosmopolitan) and others are locally distributed (i.e., endemic).

Interestingly, community composition of soil protists tends to follow patterns typically reported for macro-organisms such as the latitudinal (tendency for species richness to increase from poles to the equator) or the elevational gradient (tendency for species richness to decrease with elevation) (Geisen et al., 2018). The similarity of these patterns may further be explained by using the conceptual deterministic-stochastic framework and by considering body sizes instead of the dichotomous view of multicellularity vs

unicellularity. Deterministic processes are associated with fitness differences across organism (e.g., survival growth and reproduction) and ecological selection: abiotic and biotic factors determine the presence or absence and relative abundance of organisms. On the contrary, stochastic processes are not the consequences of environmental determined fitness, but are mostly characterized by probabilistic dispersal and random changes in community structure. Bacterial communities were reported to be relatively more influenced than larger organisms by dispersal-based stochastic processes. Larger organisms, including protists, fungi and nematodes were more influenced by selection-based deterministic processes. Within the group of unicellular protists, both stochastic and deterministic processes were reported depending on their size. Smaller protists, like bacteria, were mostly influenced by dispersal-based stochastic processes, while larger protists were mostly influenced by selection-based deterministic processes similarly to fungi and nematodes (Luan et al., 2020).

Ecological relevance

Protist trophic interactions are at the basis of most of their functional roles in the soil ecosystem. Soil protists contribute up to 70% of the total soil respiration originated from microbial eukaryotes and further participate to carbon, nitrogen, phosphorous and silicon cycles, being responsible for 14–66% and 20–40% of the C and N mineralization, respectively (Foissner, 1999).

Predation

Soil protists are mostly known for their role as main predators of bacteria. As such, protists typically reduce the bacterial biomass. Counterintuitively, however, the bacterivorous activity of protists is usually linked with an increase in microbial activity. This discrepancy is generally explained by the increased nutrient turnover that results from protist consumption as well as the removal of less active, senescent bacterial cells, which are more likely to be preyed upon first. The removal of senescent cells lowers competition for space and makes nutrients available for the more active bacterial cells.

Another crucial characteristic of protist consumption patterns is prey selectivity. In the context of bacterivory (the best described feeding preference), protists can sense and discriminate between different prey based on size, shape and chemical properties including specific membrane-bound proteins but also volatiles compounds (VOCs). Such prey discrimination and selectivity cause protists to modify bacterial community composition, favoring a specific subset of species. Noteworthy, distinct food preferences have been observed for phylogenetically closely related protists with similar morphotypes suggesting that each species has its own food preferences. Such preferential feeding is further unlikely to be very specific to only few bacterial species as the heterogeneity of the soil environment offers rather unpredictable prey community composition. It is more reasonable to expect predator protists to feed on most of the bacteria present in soils with, however, some bacterial species better fitting their nutritional needs and thus being preferred when given the choice. Thanks to such distinct preferential feeding with low overlap between protist species, the protist community is essential in maintaining a diverse taxonomical and functional bacterial community (Gao et al., 2019).

These predator-prey interactions are further likely to constantly co-evolve. As such, bacteria have evolved different strategies to escape or combat predators, including changes in bacterial cell morphology, colony formation, escaping movement and production of toxic compounds (Matz and Kjelleberg, 2005). Many toxic, anti-microbial compounds have received a lot of attention as they were primarily recognized and studied for their potential to fight various pathogens. Indeed, an important source of antibiotics comes from such research and naturally occurring anti-microbial compounds are further increasingly considered as alternatives to synthetic pesticides. These anti-microbial compounds have typically a rather untargeted mode of action and can inhibit various eukaryotes. As such, numerous compounds produced by soil pseudomonads that have long been known for their antifungal activity, such as 2,4-diacetylphloroglucinol (DAPG), hydrogen cyanide, pyrrolnitrin or phenazines, also help protect bacteria against protist predation. This observed overlap between pathogen inhibition and inhibition of predator protists highlights the role of predation pressure on the very appearance and maintenance of such biocontrol traits in the microbial community. Soil protists may thus play a valuable role in keeping soils healthy with low (plant-) pathogen densities by promoting biocontrol traits (Amacker et al., 2020).

While most studies focus on bacterivorous protists, free-living heterotrophic protists also feed on other organisms such as fungi, nematodes, and other protists (Geisen et al., 2018). Some protists became even highly specialized on a specific prey type. For example, the Grossglockneriidae, a distinct family of ciliates, feed solely on fungi: they have an adapted structure to penetrate fungal hyphae, while their cytostome does not allow the ingestion of a prokaryotic cell. In some soils, these ciliates and other obligate fungivorous protists represent a substantial proportion of the protist population likely to play important functional roles similarly to the one typically connected to bacterivorous protists (i.e., nutrient cycling and modification of the prey community composition). In addition to these highly specialized feeders, many presumably bacterivorous protists have been shown to equally ingest and grow on yeasts, as well as on spores of hyphal-forming fungi. Many protists can thus better be described as plurivorous as they can feed on different prey such as bacteria, yeasts and spores. Some protists may even be described as omnivores as they can prey on bacteria, yeasts, spores but also on higher trophic organisms such as nematodes. For example, the small testate amoebae (shell length: 17 µm, shell width: 15 µm) of the genus *Cryptodifflugia*, presumably bacterivorous, were not only able to feed and grow on yeasts, but they were even shown to collaboratively and effectively attack and prey on bacterivorous nematodes following a pack hunting strategy (Geisen et al., 2016).

Protists are eventually themselves preyed upon, channeling nutrients from small prey in unreachable pores to higher trophic predators too big to access the micro-niches (see also the Fig. 3, panel C displays such tripartite interaction). Predators of protists include a range of organisms such as nematodes, collembola, earthworms and insect larvae.

Parasites

Another important heterotrophic category of protists is 'parasite.' In soils, the most notorious group of parasites are the apicomplexans, which also include the infamous human pathogens *Plasmodium* spp., causative agents of malaria. In soils another taxonomic group of the apicomplexans, the Gregarines, is particularly diverse and abundant and they predominantly infect arthropods and other invertebrates. Parasitic protists are present in most soils, and they can contribute to more than half of the total protist diversity in tropical rainforests. In such environment, the obligate parasitic apicomplexans are suggested to play a role in controlling animal populations and local animal diversity (Mahé et al., 2017). Thus, similar to free-living, heterotrophic protists, parasitic protists might be an essential part of the ecosystem, modulating the presence and abundance of host organisms.

Some important plant pathogens are also found among soil protists. Most of the known plant pathogens are oomycetes (fungi-like protists belonging to the supergroup of the Stramenopiles). Plant-pathogenic protists have been and are still the cause of severe economic damages linked to crop losses. The oomycete *Phytophthora infestans* is a well-known infamous example as it destroyed potato fields in the mid-1840 leading to a general food crisis in Northern Europe, particularly affecting countries whose diet was primarily potato-based, such as Ireland. Especially in moist conditions, *P. infestans* is still the cause of major yield destruction if left uncontrolled. Other well-known oomycete plant pathogens include the downy mildews, *Pythium* spp. (e.g., damping off disease), *Albugo* spp., and *Plasmopara viticola*. In addition to oomycetes, the supergroup of the Rhizaria also comprises a distinct group of obligate biotrophic parasites, the phytomyxids, which include *Plasmodiophora brassicae* (clubroot disease in Brassicaceae) and *Spongospora* spp. (powdery scab in potatoes) (Geisen et al., 2018).

Several protists found in soils can also be opportunistic human pathogens. These pathogens may infect humans via ingestion of contaminated food or water, or via contaminated hands. Body openings such as the nose and eyes as well as skin lesions further offer possibilities for soil-borne protists to infect humans. Examples of such opportunistic pathogens include *Acanthamoeba* spp. causing keratitis and granulomatous amoebic encephalitis, *Balamuthia mandrillaris* and *Sappinia* spp. both also causing granulomatous amoebic encephalitis and *Vermamoeba vermiformis* causing eye infections. In addition to the direct pathogenicity of some protists, a number of amoebae have been reported to act as "Trojan horses" by hosting pathogenic bacteria, fungi and viruses. By doing so, the amoebae indirectly help the pathogens to evade measures to eradicate them or prime them to attack their host even more aggressively. A well-documented example is the bacteria *Legionella pneumophila* that can cause serious lung infection and that has been shown to be more invasive for human cells after passage through amoebae. Thus, soil is also an important reservoir and vector of human pathogens (Geisen et al., 2018).

Parasitic protists are an important component of soils with the potential to impact the presence and abundance of their host with potential consequences for ecosystem functioning. In addition, parasitic protists directly participate in nutrient cycling: by parasitizing and eventually killing larger, macroscopic hosts, they release bioavailable nutrients into the surrounding soil.

Nutrient cycling: C, N, P and Si

As highlighted above, soil protists are mostly known for their contribution to nutrient cycling as predators, but they participate to the carbon cycle at every level, from fixation to decomposition. Indeed, photosynthetic protists do occur as free-living organisms in the upper layers of soils (e.g., *Bacillariophyta*, *Chrysophyceae*, *Xanthophyceae*) and in symbiotic associations, such as with fungi in lichens (e.g., *Trebouxiphyceae*). Some soil protists even contribute to the decomposition of organic matter. Free-living, saprotrophic oomycetes, for example, decompose organic matter via the production of exoenzymes and many protists are able to take up nutrients directly from their environment via osmotrophy. Thanks to osmotrophy, *Acanthamoeba* spp. can, for example, be grown solely on nutrient-rich media without any addition of bacterial prey, allowing the generation of axenic cultures (Geisen et al., 2018).

The predator activity of soil protists is intimately linked to nitrogen. As soil protists respire, carbon is released; Because the C:N ratio of prey bacteria and fungi is either similar or lower than the one of protists, the excess nitrogen needs to be excreted by the predator protists. The important role of predators in the release of nitrogen and nutrients in general from the microbial biomass was first described under the concept of "microbial loop" in aquatic systems. A similar process was reported in soils and in particularly in the rhizosphere soil (i.e., soil under influence of plant roots). While the rhizosphere constitutes a carbon-rich environment due to the release of root exudates, nitrogen is locked up in the microbial biomass, unavailable for plants and thus limiting their growth. The presence and activity of protists is necessary to release nitrogen from the microbial biomass. About one third of the consumed nitrogen is liberated as such and becomes available to other microorganisms and plants. Indeed, an increase of up to 50% of dry weight and nitrogen content was observed for plants grown in soils containing both bacteria and protists, compared to soils lacking protists (Clarholm, 1985).

Protist activity is reported to support plant symbiotic fungi. Arbuscular mycorrhizal fungi are such plant symbionts and improve the phosphorous uptake of their host. These arbuscular mycorrhizal fungi are, however, unable to mineralize nitrogen and depend on nitrogen released in the surrounding via, for example, the microbial loop. This way, the predator activity of protists is further related to the phosphorous cycle by supporting the activity of mycorrhizal fungi (Geisen et al., 2018).

Some shell-bearing protists participate in the silicon cycle: terrestrial diatoms and testate amoebae take up silicon to build their shell, being both high silica consumers and suppliers. In some ecosystems the contribution of testate amoebae to the silica cycle is even comparable to that of higher plants, usually considered as the main contributors (Aoki et al., 2007).

In summary, soil protists contribute to every step of the carbon cycle, release nitrogen for other organisms via the soil microbial loop, thus indirectly supporting mycorrhizal transfer of phosphorous to plant, and also participate in the silicon cycle.

Soil protists in agricultural systems

Impact of agricultural management on soil protists

Protists inhabit every soil type and basically every habitat on Earth. Therefore, they are also an inherent part of agricultural soils. Agricultural soils are modified by humans with constant management to produce food, feed, fiber and fuel. As such, soil biodiversity including protists are affected in anthropogenic agricultural soils.

The first and most evident aspect managed by humans is the vegetation type, which itself strongly influences protist community composition. Each plant releases root exudates that attract a distinct microbial community comprising of bacteria and fungi, and these micro-organisms further attract predatory protists (Geisen et al., 2018). A diverse vegetation is expected to correlate with a large below-ground diversity as each plant would attract a distinct microbial community. In contrast, in human-managed areas, monocultures are expected to reduce protist diversity compared with plant rich habitats, which are expected to support and maintain greater biodiversity.

Various methods are used in the control of plant-pathogens. Different types of pesticides are thus commonly applied to protect plants against pathogens. Such pesticides are known to affect many non-target organisms, including non-pathogenic soil protists. The effects of pesticides are, however, not straightforward: some compounds directly inhibit protist viability (e.g., the fungicide azoxystrobin can reduce the density of ciliates and flagellates), while others such as glyphosate can stimulate bacterial growth and potentially further support protist growth. In addition, the effects of pesticides typically vary between protist species and are dose dependent, i.e., depend on the concentrations of the tested compounds (Lo, 2010). While it is clear that chemical compounds can affect soil protists, the extent of the impacts and the ecological consequences remain largely unknown.

To increase yield, the addition of fertilizer is also common in agricultural soil and protists are reported to be particularly affected by such addition. Such effects are mostly indirect: protist diversity was, for example, reduced following modifications of abiotic properties (Zhao et al., 2019). Which specific taxa was favored or reduced was related to the soil type (red soil, fluvo-aquic soil or black soil) and the sampling season (summer or autumn); bacterial and fungal communities only varied between soil types but not with season nor due to fertilizer application. These findings highlight a particularly dynamic response of the protist population to environmental change.

In general, any type of soil management is expected to affect the protist community composition through modifying soil structure and physicochemical properties as well as the above- and below-ground biodiversity. It is also increasingly recognized that soil protists may be more strongly affected compared with lower trophic levels, such as bacteria and fungi, thus deserving a particular focus. Indeed, due to their dynamic response to environmental changes and their pivotal role in the food web, soil protists possess a unique potential to monitor the effect of agricultural practices on the soil microbial biodiversity and functionality.

Soil protist to support plant performance

A better understanding of the protist ecology in natural and managed soils could lead to improved soil health. Indeed, plant performance is intimately linked to its microbiome. While the focus is usually centered on bacteria and fungi, protists are also essential partners of the plants.

In general, the presence of an abundant and diverse protist community should support a greater nutrient turnover (due to the microbial loop in soil) and a diverse prey community (due to preferential feeding). While predation by protists typically induces changes in the bacterial community composition due to preferential feeding, it is also expected to generally prevent the dominance of few fast-growing bacteria, thus allowing for a more diverse bacterial community composition including rare taxa. Supporting diverse and abundant protist communities thus enables a more efficient use of organic fertilizers and should favor a greater functional diversity. Better ecological knowledge and technological development may even allow the enhancement of specific, targeted microbiome functions by exploiting the feeding preferences of protists. The application of protists has been already shown to increase the survival and plant-beneficial activity of different plant-growth promoting bacteria (Gao et al., 2019).

The increased survival of plant-growth beneficial bacteria in presence of predators is likely related to their ability to either escape their predators (e.g., high speed motility, biofilm formation) or to fight back via the production of anti-microbial compounds. Anti-microbial compounds produced by bacteria to inhibit their predators also affect many other eukaryotes (incl. Plant pathogens), therefore acting as biocontrol agents. In addition to benefiting plant growth, soil protists may thus be used to support plant health. The presence of predator protists can affect the ability of the soil microbiome to reduce plant pathogens in multiple ways. First, presence of protists induces the production of anti-microbial compounds. Second, protists may further support the successful establishment of biocontrol bacteria in soils because the predator protist is expected to preferentially feed on undefended, non-toxic bacteria, thus lowering the competition in favor of the biocontrol agents. Third, protists may indirectly prime plant immune response as a response to over-produced antimicrobial compounds as a bacterial defense strategy. Finally, protists can directly contribute to disease suppression by consuming or parasitizing pathogens, reducing their survival in soil and potentially protecting plants (Gao et al., 2019).

Soil protist as bioindicators

Because of their link to plant growth, their unique nature (e.g., rapid growth rate, small size, delicate external membranes) and position in the food web, soil protists have been suggested as indicative of soil status and functioning. Such potential as bioindicators was first highlighted in protist groups displaying specific morphological traits enabling easier identification. Thus, ciliates which are in general more easily counted and identified than other protists, could be used as bioindicators in polluted and degraded soils (Foissner, 1999). Another group of protists was recognized as valuable indicator in soils: the shell-bearing testate amoebae. They are used to distinguish between different humus types (i.e., mor, moder and mull) and further to infer other environmental changes, such as pollution, land use, fire history, nutrient status, and even as forensic indicators for dating the time of death. In addition, thanks to the relative high resistance of their shells to decay and the presence of distinct features enabling identification, testate amoebae are often used to reconstruct the water table in peatlands. Such studies enable the reconstruction of the paleo-environment to better understand effects of climate change (Geisen et al., 2018). With the technological advancement of the last decades, it has become possible to study the response of not only ciliates and testate amoebae, but of the general soil protist population. It was demonstrated that not only do protists respond dynamically to environmental changes at the community-level, but they are even more sensitive than lower trophic organisms such as bacteria and fungi (Zhao et al., 2019).

In addition to their indicative potential for soil status, soil protists are suggested as model organisms for ecotoxicological bioassays to predict the effect of various biocides, including pesticides used in agriculture and other pollutants that unintentionally reach the soils. Some bioassays have been used to test, for example, the effect of pesticides on *Dictyostelium discoideum* or the influence of heavy metals on ciliates (Geisen et al., 2018). Such bioassays using protists have already been developed and are used in aquatic systems to evaluate the toxicity of various chemicals (e.g., with the freshwater ciliate *Tetrahymena pyriformis* or various green algae), but to our knowledge none are routinely used to assess impacts of biocides in soils.

While the validity of methods using soil protists is usually accepted, practical applications are still limited by the difficulties related, for example, to time-consuming morphological identifications. In addition to the time limitation, only few skilled specialists can accurately identify the protists, thus strongly restricting its usage. Simplified direct observations, approaches based on functional traits and development of new molecular screening tools are likely to be necessary to enable the routine application of soil protists as indicators of soil health (Geisen et al., 2018).

Conclusion

Soil protists are now increasingly recognized as an abundant, diverse and essential component of the soil ecosystem. Evidence for both global and endemic distributions have been reported, as well as various diversity patterns related to environmental variables or biotic interactions. Predator and parasitic protists determine their prey or host community composition and activity. At the same time, protists drive the cycling of nutrients, including carbon, nitrogen, phosphorous and silicon. Finally, soil protists are an inherent component of agricultural soils, dynamically responding to soil managements and having the potential to be both detrimental and beneficial to plants, animals and humans. Understanding the ecology of soil protists will help us supporting a healthy and diverse soil ecosystem.

The true diversity of soil protists, however, remains unknown. Identifying and describing this huge taxonomical diversity is thus still an important agenda. In addition to the taxonomy, the ecological role of protists has been revealed as essential for soil status, but many aspects are still ambiguous. For example, it is clear that protists induce distinct modification of their bacterial prey community composition, but the mechanisms behind this apparent preferential feeding have not yet been fully identified. This prevents us from fully harvesting the potential of protists in supporting a beneficial soil microbiome. Finally, it is also essential to recognize and investigate the unique contribution of each protist species and start linking them to functional traits that enable approaches focused on their ecological roles. Altogether, we conclude that protists can be considered as a rising star in soil biodiversity research with future studies undoubtedly deciphering their full complexity in the ecosystem.

Abstract

The morphological, reproductive and physiological traits of fungi are presented, followed by their contrasting biotic interactions with organisms living in soils, particularly mycorrhiza (the symbiotic associations with plant roots) that are crucial to the functioning of terrestrial ecosystems. Their broad range of metabolic capacities indicate that fungi are a main group of the soil microbiome, importantly participating in pedogenesis and element cycling, and of the plant holobiont. Recent integration of microbiological, physiological, new molecular ecological techniques and bioinformatics has dramatically increased knowledge of soil fungi, their role in soil functioning and potential development of more sustainable soil and land-use practices.

Introduction

Fungi are ubiquitous in soils, but comprise a varying proportion of the microbial biomass in different ecosystems and soil horizons. They tend to dominate over bacteria in soils rich in organic matter but constitute a smaller proportion in intensively managed and mineral soils. They are involved in a plethora of functional roles, encompassing biological, chemical, and physical interactions, and are of great ecological and economic significance. The study of fungi is termed mycology (after *mukēs*, Greek for ‘fungus’).

Classification

The ‘true fungi’ belong to the kingdom of Fungi and are eukaryotic, exclusively heterotrophic organisms with cell walls that contain chitin or chitosan as a major constituent for almost all taxa, and typically have a thread-like hyphal growth-form, although unicellular forms are common in the yeasts (Richards et al., 2017). Recent multigene analyses separate

19 phyla: Aphelidiomycota, Ascomycota, Basidiobolomycota, Basidiomycota, Blastocladiomycota, Calcarisporiellomycota, Caulochytriomycota, Chytridiomycota, Entomophthoromycota, Entorrhizomycota, Glomeromycota, Kickxellomycota, Monoblepharomycota, Mortierellomycota, Mucoromycota, Neocallimastigomycota, Olpidiomycota, Rozellomycota and Zoopagomycota (Wijayawardene et al., 2020). The former Fungi imperfecti, lacking a sexual phase, are now ascribed to different phyla. Representatives from most phyla are commonly found or can be expected in soils, where fungal biodiversity and density are greater than in aboveground ecosystem compartments and vary differently among geographic gradients than do other taxa (e.g. plants) (Teder et al., 2014).

Biology

Morphology and form

A fundamental characteristic of the filamentous (eucarpic) fungi is their growth-form, which consists of thread-like hypha, growing by apical extension and periodic branching to form a mycelium that permeates the environment explored by the fungus (Fricker et al., 2017) and Fig. 1A–E. The diameters of individual hyphae vary according to age, species, and nutritional conditions but are typically 3–10 µm. In extreme cases, up to 2 km of hyphae per gram of soil have been measured in some soils; a typical cultivated arable soil contains several meters per gram. Mycelia are indeterminate structures that grow in three dimensions and therefore conceptually are difficult to size. In soil, they may occupy almost any volume, and the largest organisms on the planet are probably mycelia of *Armillaria bulbosa*, individual clones of which are reported to extend continuously over tens of hectares in North American forests (Fig. 1G) (Smith et al., 1992). In Asco- and Basidiomycota, hyphae are generally compartmentalized by cross-walls (septa), which occur at varying intervals depending on species (Fig. 1B). Septa may be complete or perforated to varying degrees and play a role in regulating the passage of materials, including organelles, between adjacent compartments. In particular, tubular vacuoles, extend through pores and by their pulsating activity, they control directed transfers of solutes between hyphal compartments. If mycelia are fractured, septal pores become occluded, which prevents leakage of cytoplasm from the open ends. In certain phyla such as Glomeromycota and Mucoromycota, mycelia have almost no septa and are largely coenocytic (multinucleated).

Hyphae may aggregate to form higher-order structures such as strands (cords; Fig. 1E) or rhizomorphs, which enable long-distance foraging (decameters in the case of woodland basidiomycetes) (Agerer, 2001). Hyphal aggregation and differentiation can also produce morphologically complex macrostructures such as the intricate fruiting bodies (basidiocarps) of some Basidiomycota or ascocarps of some Ascomycota.

Those fungi that do not form hyphae (predominantly yeasts) have a holocarpic growth form, comprising individual cells that replicate by budding or binary fission. Some fungi are dimorphic and can switch between holocarpic and eucarpic growth forms depending on environmental conditions (e.g., *Mucor hiemalis*).

Physiology and reproduction

All fungi are obligate heterotrophs, i.e., they utilize fixed (organic) C sources as substrate (Carlile and Watkinson, 2001). Across the kingdom an extremely wide range of compounds can be utilized, ranging from C1 compounds (methylotrophic yeasts) through to lignin and industrially produced polyphenols – almost any natural or synthetic ring macromolecule occurring in soils can be degraded by some fungi. A concomitantly wide range of enzymes is secreted locally by hyphae, and thus targeted metabolic capabilities are expressed at the vicinity of or within specific substrates, which is regulated by nutrient availability in each micro-niche (Schinner et al., 2012). This makes mycelia highly efficient and flexible nutrient acquisition systems, well adapted to the heterogeneity of soils in time and space (Dighton et al., 2019). Respiration can be aerobic or anaerobic, with obligate or facultative types of both forms occurring. Some fungi obtain their nutrition from other living organisms (plants, animals, other fungi) via parasitic or mutualistic associations, whilst others are saprotrophs (Carlile and Watkinson, 2001). Many soil fungi are very efficient scavengers of nutrients and grow sparsely but effectively under the oligotrophic conditions that prevail in many soils. A wide variety of secondary metabolites are produced by soil fungi, including many volatile organic compounds (VOCs), which may act as signals or substrates as they diffuse through pore networks (Macheleidt et al., 2016). If fungal spores or mycelial fragments are added to nonsterile soils, they rarely germinate. This phenomenon, known as fungi stasis (or mycostasis) is probably due to an inadequate supply of available nutrients (the extant microflora normally having depleted the microbially available nutrient pool), the presence of inhibitory (antibiotic) compounds produced by the existing microflora or a combination of both (Garbeva et al., 2011).

Reproduction can be sexual or asexual, and a variety of mating systems occur (Hawker, 2016). Many fungi have genetic systems that prevent mating between genetically identical cells or mycelia. If hyphae encounter each other, they may fuse (anastomose). If they are somatically compatible, the fusion results in the formation of larger mycelial networks, with attendant functional consequences in terms of spatial exploration, activity, translocation, and combativeness. Somatic incompatibility, however, results in a rejection response, and the cytoplasm in fused compartments is destroyed. Fungal propagules generally take the form of asexual or sexual spores, sclerotia (dense, heavily pigmented hyphal aggregations), or hyphal fragments. Some species sporulate very profusely (e.g., *Penicillium*), others have never been known to produce any form of spore (e.g., *Rhizoctonia solani*). In soil, propagules are dispersed by mass flow in soil water, carried by animals internally or externally to their bodies, or via physical (often faunally mediated) soil movement.

Biotic interactions

In soils, as in other environment compartments, no organism grows in isolation, but always in the context of a wider microbial community, and soil organisms have evolved under such circumstances over millions of years. It is not surprising, therefore, that there are extensive interactions between soil fungi and all other classes of organisms, including other fungi, bacteria, protozoa and viruses. At present, we only have a limited understanding of the degree and nature of such interactions, since the majority of microbiological research has been on the growth and physiology of microbes often cultivated in isolation, or in simple combination, and often in vitro. But the ecological importance of interaction networks among fungi and with members of other kingdoms is actually considered in the emerging concepts of soil microbiomes and holobionts (Fierer, 2017).

Fungal associations with other microbes

Fungal associations with algae or cyanobacteria, in the form of lichens with combination specific morphology, play a role in soil genesis via rock weathering (Jackson, 2015). Bacteria can also glide at the surface of fungal hyphae colonizing and connecting soil compartments. In soils proper, when fungal mycelia meet, there can be a variety of outcomes from such interactions. If they are somatically compatible, they will fuse to form a larger mycelium (see above); other outcomes include an intermingling without fusion, chemically mediated repellence, physical exclusion by the development of insulated barriers, or death and replacement of one mycelium by the other (Fricker et al., 2017). There are complex hierarchies of combativity between different species and strains, and environmental factors such as temperature, water, pH, and nutritional status impact the balance between niche conditions and stochasticity in shaping community composition of soil fungi (Beck et al., 2015). Fungal communities in soil are therefore in a state of perpetually responding to stress and interaction. There are also many examples of specifically hyperparasitic fungi (e.g., *Arthrobotrys oligospora*, *Coniothyrium minitans*) and bacterial mycoparasites (e.g., *Pseudomonas* spp.). Mycoviruses do not have an extracellular phase, and since they do not necessarily affect the fungal phenotype they may be more prevalent than was thought hitherto.

Fungal associations with plants

Plants are the primary autotrophs in terrestrial systems and therefore responsible for most deposition of fixed C into soils. Litter input and root exudation provide the majority of substrate for the heterotrophic fungal soil biomass. Biotic associations between vascular plants and fungi are extensive.

Mutualism

Mutualistic associations between plant roots and fungi are termed ‘mycorrhizas’ (Fig. 2A–E) and first evolved, almost simultaneously, with the emergence of land plants (Smith and Read, 2010). Such associations are extremely common, and the natural state for the majority of root systems is to be infected to some extent by mutualistic fungi. Seven major types of mycorrhizal association exist that differ anatomically and physiologically and have variable host ranges (Table 1). In the majority of cases, the fungal partner derives carbon from the host, and the plant benefits from a more secure uptake of nutrients such as P or N and water, mediated by extensive external (extraradical or extramatrical) mycelia. In some cases, however, non-chlorophyllic plants receive organic carbon from their mycorrhizal partner (mycotrophism). Mycorrhizal infection may also confer resistance against pathogens and abiotic stresses such as drought or toxic metals. Given that most soil microbes are C-limited, it is likely that mycorrhizal hyphae constitute a significant proportion of the fungal biomass in vegetated soils, since they are intimately associated with a readily available source of C via their host plants. Mycorrhizas strongly affect the competitive ability of plants (often mediated via nutrient acquisition) and thus play a role in governing the community structure of vegetation. Mycorrhizal networks can infect a number of plants of the same or different species simultaneously and thus form an interconnected common mycelium network, providing the possibility for nutrient and signal molecule transfer between plants via interconnecting hyphae (Johnson and Gilbert, 2015). For example, it has been suggested that arbuscular mycorrhiza influence the acquisition of mineral phosphorus either positively or negatively among plant communities via common mycelium networks (Smith et al., 2011). Research on the ecological significance of such phenomena is still in its infancy. The network of extraradical growing hyphae of mycorrhizal fungi, also affects soil formation and functioning. Owing to its particular role, especially in forests, in relating plants and soil compartments and acting as nutrient, water and information transfer channels, this fungal network is a central element of what has been termed the “wood wide web” (Simard and Durall, 2004). Mycorrhizal fungi that also have saprotrophic potential (e.g., ectomycorrhizal) have a competitive advantage over exclusive saprotrophs. In forest biomes dominated by ectomycorrhiza, this competitive advantage lowers the litter turnover and triggers accumulation of organic matter (Fernandez and Kennedy, 2016). Vice versa, arbuscular mycorrhiza are obligate biotrophs and have no direct saprotrophic capabilities. Biomes where they dominate are characterized by high levels of litter decomposition and accumulate less soil organic matter.

Parasitism

Plant pathogenic fungi cause very significant economic losses to crops in both temperate and tropical agricultural and forestry systems (Doehlemann et al., 2017). They also occur in natural systems and play a role in mediating plant community structure,

Fig. 2 Mutualistic associations involving soil fungi. (A) Infection point of arbuscular mycorrhizal (AM) fungus on root of *Plantago lanceolata* (plantain). although relatively little is known about the extent of such regulation. Such fungi can have biotrophic, necrotrophic or hemibiotrophic life styles (Horbach et al., 2011). Importantly, whereas plant fungal pathogens are less virulent in species-rich plant communities, they cause serious diseases in intensive crop monocultures.

Soil-borne plant pathogens occur across almost all fungal taxonomic groups and vary in their host specificity (Crous et al., 2015); important examples include *Gaeumannomyces graminis* (take-all of wheat; Fig. 2F), *Rhizoctonia solani* (root and stem rots, including potato tubers, with a wide host range), *Armillaria mellea* (honey fungus, with a wide host range of trees), *Fusarium oxysporum* (a wide variety of forms, which affect specific plants – e.g., *F. cubense* causes wilt in banana).

The primary site of infection for soil pathogens is normally roots, although some pathogens attack the hypocotyls or stem bases of plants on or near the soil surface, and there are a range of tuber diseases. Many pathogens show strong taxis toward roots, mediated via soluble or volatile exudates, or electrical charges (electro-taxis). The pathogenic mode of action takes many forms between different pathogens, from necrotrophic attack and wholesale degradation of tissue, through cortical invasion, root hypertrophy, to the blocking of vascular tissue and hence interference with water and solute transport (wilts) (Horbach et al., 2011). There is often a proliferation of mycelia on root surfaces prior to penetration via localized aggregations of hyphae (infection cushions).

Table 1 Basic characteristics of the seven mycorrhizal types (see Smith and Read (2010) for details).

Mycorrhizal type	Habit	Host range	Examples	Notes
Arbuscular (AM)	Endotrophic; form arbuscules and sometimes vesicles in root cortical cells	ca. 90% of vascular plants; exceptions include members of Brassicaceae	Exclusively Glomeromycota (e.g. <i>Glomus</i> , <i>Gigaspora</i> , <i>Acaulospora</i>)	Obligate biotrophs; can only be cultured in association with plants (including root-organ tissue culture systems)
Ecto- (ECM)	Ectotrophic; form extensive mycelial mantles around root, penetrate between cells of root cortex to form a Hartig net)	Mainly woody plant of boreal and temperate regions but also some major tropical trees	Basidiomycetes (e.g., <i>Amanita</i> , <i>Suillus</i>); Ascomycetes (e.g. Tuber); some Zygomycetes (Endogone)	Also grow saprotrophically in absence of host plant, and in pure culture
Ectendo-	Ectendotrophic; same anatomy as ECM but with penetration into root cells	Young trees such as spruce, frequent in nurseries	Ascomycetes (e.g. <i>Cenococcum</i>) Basidiomycetes	Same as for ECM
Arbutoid	Ectendotrophic; same anatomy as ECM but intense penetration into root cells	Essentially mediterranean Ericaceae of the genus <i>Arbutus</i>	Basidiomycetes and Ascomycetes that form ECM on neighbor trees	As <i>Arbutus</i> resists forest fire, it helps ECM formation on trees regenerating burnt forests
Monotropoid	Ectendotrophic; same anatomy as ECM but with penetration into root cells limited to hyphal pegs	Exclusively achlorophyllous plants that parasitize tree roots (e.g. <i>Monotropa</i>)	Basidio and ascomycetes forming ECM on the parasite host tree	Mycotrophy: transfer of carbohydrates from the parasitized ECM host tree via the common mycelium
Ericoid	Endotrophic; intracellular coils formed inside host cortex	Ericaceae	Hymenoscyphus, Oidiodendrum	Occupy up to 80% of root cell volume, almost no extra-radical mycelium. Secrete acid proteinases that attack recalcitrant litter in acidic soils
Orchidoid	Endotrophic; short-lived intracellular coils in host root cells	Seeds and achlorophyllous orchids	<i>Rhizoctonia</i> , <i>Marasmius</i>	Mycotrophy: provide carbohydrates to orchid seed endosperm for stimulating growth of the protocorm, on which plant embryos differentiate

Control of root pathogens is often based upon use of resistant cultivars, crop rotation to mitigate build-up of pathogen populations, and appropriate soil management such as crop rotation and tillage practices, organic matter incorporation, or liming. Persistent growth of the same cereal crop can result in so-called take-all decline, where disease severity is reduced after several seasons, due to the build-up of microbial communities that are antagonistic to *Gaeumannomyces*. Chemical control is rarely feasible due to the buffering capacity of soil against bioactive compounds and the rapid degradation of such compounds by the soil microflora.

Fungal associations with fauna

Fungal associations with soil fauna are extremely common, including a wide range of mutualistic and parasitic relationships. For example, in predatory, nematode-trapping species (e.g., *Arthrobotrys* and *Dactylella* spp.) an extensive variety of mechanisms to procure their prey has evolved (Su et al., 2017). This includes sticky hyphae, branches, nets, and knobs, which are sufficiently adhesive to prevent escape of nematodes prior to digestion by the fungus (analogous to insectivorous sundew plants), and hyphal rings (lassoes), some types of which contain inflating trigger cells, which grip the bodies of prey to prevent escape (Fig. 2G). Other fungi (e.g., *Verticillium* spp.) infect nematodes via spore attachment and hyphal penetration of cysts, juveniles, or adults. Virtually all insects studied to date appear to have a range of parasitic and mutualistic (principally in their guts) fungi associated with them (Wang and Wang, 2017), including during larval and pupal stages by vertical transmission. Fungal hyphae and spores are also attacked or grazed by representatives from most faunal groups, including protozoa, nematodes, worms, insects, and mites (Crowther et al., 2012). Subtle interactions occur. For example, there is a wide variation in the degree of palatability of different fungi to different fauna, which results in preferential grazing of mycelia by soil fauna, analogous to aboveground herbivory (Bonkowski et al., 2000). Soil fauna play a strong role in dispersing fungi through soil, either as spores attached to their bodies or via egestion in feces at sites remote from where the fungus was ingested. Some Basidiomycetes (e.g., *Termitomyces*, *Acromyrmex*, *Leucoagaricus* spp.; Fig. 2H) are 'farmed' by termites and ants, maintained within the insect colonies in essentially pure culture on imported plant material.

Microbiome and holobiome

Microorganisms are intermingled in their functioning within the plant-soil ecosystem (Vandenkoornhuysen et al., 2015). Mycorrhiza helper bacteria support fungi in forming mycorrhiza (Frey-Klett et al., 2007), and nitrogen-fixing bacteria support the activity of fungi in decaying dead wood (Hoppe et al., 2014), a substrate with very sparse available nitrogen resources. More generally, every biogeochemical transformation or cycling activity in soils involves dynamic communities of interacting microorganisms, which

comprise, in addition to fungi, protozoa, archaea, bacteria and viruses. These inter-kingdom microbial communities constitute the “soil microbiome,” and the community structure and functions of these complex biocoenoses can now be explored with soil molecular ecological approaches (see below). Similarly, for larger multicellular organisms such as animals and plants, the concept of holobiont has emerged, which considers the sum of these organisms plus their associated microbiomes as functional and evolutionary entities (hologenomes) (Zilber-Rosenberg and Rosenberg, 2008).

Fungal contributions to soil-system formation and function

Soil formation and pedogenesis

Soil formation (pedogenesis) occurs via concomitant weathering of parental rock and decay of plant residues, accompanied by selective vertical transfers and edifications of complexes between the minerals and organic fractions that result from the two processes. Physical, chemical and biological factors drive these intermingled transformation and complexation steps, and fungi contribute to the three levels. So called rock-eating fungi, free-living or in lichen or mycorrhizal associations, contribute to the weathering of parental rock material and bore micro-tunnels at rock surface, which opens the way for their physical fractionation into smaller particles with enhanced chemical reactivity. Fungi are major agents of plant residue transformation, and the biomolecules produced during the decay of their own necromass enter into the composition of the stable soil organic matter (humus). As described below, fungi are also crucial contributors to formation and stabilization of mineral-organic complexes and soil aggregates (Rillig, 2004).

Nutrient cycling

Soil fungi play a crucial role in nutrient cycling in terrestrial systems, due to the primary role they play as decomposers, mediated by a large repertoire of catabolic enzyme activities (Waring et al., 2013). They are particularly involved in cycling C, N, and P, but have roles in most of the other soil elemental cycles (Read and Perez-Moreno, 2003). Fungi are primarily involved in the decomposition of plant material, the lignocellulosic components of which are relatively recalcitrant to bacteria. There is typically a succession of fungal (and other microbial) species on new substrate when it enters soil, based upon the initial decomposition of simpler compounds and a subsequent degradation of more complex polymers (Purahong et al., 2016). Cellulases are produced by a wide variety of fungi across the taxonomic classes; these include the brown rots, so-called because their activity results in a darkening of wood as the cellulose is decomposed and lignin (which they are not able to decompose) remains. Within fungi, polyphenol oxidases (mainly laccases), and mangan- or lignin-peroxidases involved in the decomposition of lignin, are largely confined to Basidiomycetes and some Ascomycetes. These include the white rots species, which normally also have strong cellulase activity but render wood a light color during selective lignin decay.

As well as invoking the enzymatically mediated degradation of polymers, many fungi also produce a variety of compounds such as organic acids or siderophores, which solubilize or immobilize essential or toxic metals, with consequences for both their own growth and the growth of proximal organisms (Priyadarshini et al., 2021). Fungi also act to immobilize nutrients in soil through sequestration in mycelia, which are further released following death and lysis or attack by pathogens or grazers. Eucarpic fungi play a significant role in physically transporting nutrients through the soil fabric via translocation within mycelia, thus short-circuiting other diffusion and mass-flow transport mechanisms, both in saprotrophic and mutualistic (mycorrhizal) contexts. Soil humus was long considered to consist in partly degraded and transformed plant residues, but is now recognized as residual biomolecules of microorganisms and hence, in large part, originate from fungi, that are the main contributors to humus formation (Liang et al., 2020).

Soil architecture

Eucarpic fungi influence soil structural dynamics via a number of mechanisms and on different spatial scales. Hyphal networks enmesh soil particles together, rather like the bars in reinforced concrete. Sparse mycelia in nutrient-poor mineral soils are unlikely to be particularly influential in this respect, but the dense mycelia that can form where substrate is abundant, for example in forest litter layers, can be quite resistant to physical disruption. These mechanisms operate on scales of millimeters to centimeters. The variety of compounds exuded by hyphae as they grow bind soil particles together via adhesive or charge-based mechanisms, on scales from nanometers (charge) to millimeters (adhesive). Such binding results in increased aggregation of soil and an associated structural generation. Degradative enzymes prevalent near hyphal tips may also decompose organic matter binding soil particles together, resulting in structural de-generation. Fungi produce large quantities of a diverse array of hydrophobic proteins (hydrophobins), which serve to insulate hyphal walls. This is important due to the large surface area-to-volume ratio that arises from the mycelial growth-form. However, these compounds also coat soil particles and can strongly influence the water sorptivity and repellency characteristics of the soil. This in turn affects the hydraulic properties on larger scales. It has recently been suggested that glomalin, a glycoprotein produced in abundance by arbuscular mycorrhizal (AM) fungi and which is resistant to decomposition, may play a key role in effecting mechanisms of adhesion and soil stabilization (Rillig, 2004). As hyphae extend through soil, they may also cause physical restructuring of soil, by rearranging particles, and orientate clay lamellae parallel to their walls (Fig. 3).

Fig. 3 Orientation of kaolinite clay platelets by hyphae of *Chetomium* sp. Scale bar 2 μm . Reproduced with permission from Dorioz JM et al. (1993) The role of roots, fungi and bacteria on clay particle organization. An experimental approach. *Geoderma* 56: 179–194.

Although fungi certainly affect soil structural dynamics, the physical architecture of the soil also affects fungal growth in that it provides the physical framework through which fungi must grow to locate resources. The eucarpic growth-form is particularly effective for growth in such spatially structured environments, where complex pore networks prevail and water and substrate are distributed in a heterogeneous manner within the three-dimensional matrix. Hyphae are able to grow across the surfaces of pore walls but also bridge wider pores; since mycelia form an interconnected network, materials can be transported within them from zone to zone, potentially supplementing growth factors where they are in demand in particular regions. Translocation within most soil fungi is yet poorly understood. There is evidence that different materials can be simultaneously transported in opposite directions within mycelia. Most substrate in soils is distributed patchily, and path lengths between resource depots can be extended greatly by the tortuosity of pore networks. Many species show foraging strategies, which balance explorative and exploitative growth strategies relative to the distribution of resources encountered in their normal habitats. Such strategies are highly developed in the cord-forming Basidiomycetes. Physical exclusion mechanisms, where pore diameters are too small to permit penetration by hyphae, probably operate; the extent to which hyphae can physically separate soil particles to allow penetration, akin to plant roots, is largely unknown. Physical protection of organic matter and organisms (including hyphae) from degradation or predation via such spatial exclusion also occurs. Hyphae are generally poor at growing through water-filled pores and hence are less prevalent in waterlogged soils. There are thus strong interactions between soil structure, water, and mycelial growth.

Methods of study

A comprehensive range of methods has been developed and applied to study the presence, abundance, activity, and distribution of fungi in soils. ‘Quantification’ of soil fungi presents a particular challenge, since there is a diversity of functionally important components, ranging from total hyphal length through mass of cytoplasm and number of propagules (Bridge and Spooner, 2001). Methods must be carefully matched to the nature of the study being undertaken. A limitation is the time investment required for each analytical approach. Time-consuming approaches only permit analyses of limited subsets of samples, which only enable us generating small data sets, which do not reflect the high heterogeneity and multi-compartmentation of soil habitats, only provide indicative insights and preclude large scale monitoring or studies.

Isolation methods

A wide diversity of fungi can be isolated from soils by traditional methods of dilution plating and enrichment growth on broad-scale or specific gel-based media supplemented with a variety of nutrient sources. These range from oligotrophic (based on silica gels, which are devoid of organic compounds) through to C-rich media such as Czapek-Dox medium (an agar gel based on 3% sucrose). Since relatively small dilutions of soil are often necessary compared with those appropriate for bacteria (typically 10^{-3} in contrast to 10^{-5}), media may be supplemented with antibacterial compounds to inhibit contaminating overgrowth. Many soil prokaryotes are apparently not cultivable in vitro, but the extent to which the ‘noncultivability syndrome’ may apply to soil fungi is unclear. Although such plating methods may be appropriate to determine fungal richness (i.e., a basic range of cultivable species

present), meaningful interpretation of 'colony-forming units' (CFUs) by such means is often dubious. This is because colonies can form from hyphal fragments as well as from spores, and the number of CFUs will therefore be strongly affected by the propensity for, and degree of fragmentation of, mycelia during sample preparation – it is difficult to relate this to the probable status of any mycelia in the soil. In addition, the expression of colonies on media can be dependent on the presence or absence of other species within the same plate. Soil fungal colonies with a high sporulation rate, such as *Penicillium*, tend to be overestimated in quantification analyses based on isolation. In addition, the numerous dormant spores of non-active fungal colonies, which germinate on isolation media bias the characterization of active soil fungal communities. Techniques to wash out spores prior to isolation help to circumvent such biases. Hyphal fragments or (larger) spores can be directly extracted from soils by micromanipulation, on density gradients or by elutriation and sieving. 'Baiting' methods are based on the insertion of sterile substrates such as gel-filled perforated tubes, cotton strips, or hair into undisturbed soil, followed by removal and isolation of fungi colonizing these substrata. If an air gap surrounds the baits, it is assumed that any fungi entering them were in an active hyphal state in the soil.

Direct observation

Measurement of total hyphal length is possible by direct observation of thin films of dispersed soil using a microscope. It is normally necessary to stain hyphae using colored (e.g., aniline blue, acid fuchsin) or fluorescent (e.g., Mg ANS, an 8-anilino-1-naphthalene sulfonic acid salt; Fluorescent Brighteners – FB24, also known as Calcofluor W M2R) stains to render them visible against the complex background of soil particles. Metabolically active hyphae can be distinguished from inactive forms by use of vital stains such as fluorescein diacetate (FDA) or tetrazolium dyes. By measuring hyphal diameters as well, estimates of bio-volume and thence biomass can be made using conversion factors. Soil films can be produced by smearing small volumes of suspension onto glass slides or pulling suspensions down onto membrane filters. Soil thin-sections, produced by impregnation of undisturbed soil with hard-curing resin, and cutting and polishing the resultant blocks with lapidary (jeweller's) pastes, enable the in situ observation of fungal features (Fig. 4). Computerized image processing and analysis can be used to automate identification and measurement procedures, but such methods rely on a high degree of contrast being obtained between hyphae and background. It is rarely possible to identify fungi by these methods, since most hyphae do not have a sufficiently distinct morphology.

Fig. 4 Fungal features visualized in thin sections of undisturbed soil. (A) Hyphae of *Rhizoctonia solani* predominating in soil pores. Scale bar 100 μm ; (B) unidentified mycelium in grassland soil showing extensive branching in soil pore, and associated sporophores. Scale bar 50 μm ; (C) perithecial of unidentified fungus embedded in cortex of root in thin-section of arable soil (note orientation of orifice through which spores are released into soil pore). Scale bar 50 μm ; (D) accumulation of fungal spores in vicinity of decomposing root (located in lower-right quadrant of image). Scale bar 50 μm . Reproduced with permission from Karl Ritz, David Crabb, Kirsty Harris, ScottishCrop ResearchInstitute.

Infection of roots by AM fungi is normally assessed by direct microscopic observation of roots cleared of cytoplasm by treatment with alkali, and stained using dyes such as trypan blue or chlorazol black E. Morphological and anatomical morphotyping of ectomycorrhizal roots permits characterization of the diversity and frequency of ectomycorrhizal fungi and, when connections to fruiting bodies exist, even their identification. Analyzing the network, ramification and length of rhizomorphs attached to mycorrhiza also provides an insight into the proximate to distant soil compartment from which ectomycorrhiza mobilize plant nutrients.

Physiological and molecular methods

Complementary to cultivation and direct-observation techniques are so-called molecular analyses, which focus on biochemicals that are more or less specific to fungi. These methods circumvent many of the problems associated with *in vitro* cultivation of fungi and offer a wide range of scales of resolution in quantitative analysis. Total fungal biomass in soils can be estimated by direct extraction and measurement of biomarker compounds such as chitin, ergosterol, phospholipid fatty acids or DNA (Baldrian et al., 2013). The effectiveness of this approach relies on such compounds being specific to fungi and present in a constant proportion relative to the amount of biomass. Few compounds meet these criteria strictly. For example, chitin is also present in arthropods and ergosterol concentrations can vary significantly depending on the age, nutritional status, and species of fungus. More potential is shown by phospholipid fatty acids (PLFAs); these membrane-bound compounds vary in composition with reasonable consistency between different organisms, can be readily extracted from soils and have wide-ranging PLFA profiles determined by gas chromatography and mass spectrometry. PLFA 18:2 ω 6,9 and 18:1 ω 9 are as fungal indicators for Mucoromycotina, Ascomycota, and Basidiomycota, but presence of plant material creates biases. PLFA 16:1 ω 5 is apparently specifically associated with AM fungi. Immunological techniques based on polyclonal or monoclonal antibodies, particularly via the enzyme-linked immunosorbent assay (ELISA) can be used to detect the presence of specific fungi in soil samples.

Analysis of nucleic acids directly extracted from soils has revolutionized soil ecology, including soil mycology (Sandrini et al., 2022). With burgeoning knowledge of the specific nucleic acid sequences associated with particular fungi, especially in relation to ribosomal DNA (rDNA; for fungi typically 28S, 18S, and 5.8S, and associated internally transcribed spacer, ITS, regions), it is possible to prescribe probes that detect fungal DNA with virtually any degree of specificity, from the broadest of scales to strain-specific. Such probes can be labeled with fluorescent, radioactive, magnetic, or enzyme tags, which can enable their direct detection in soil-based systems. Application of the polymerase chain reaction (PCR) can enable the detection of extremely small concentrations of specific DNA sequences in complex environmental samples and can also be used in a broad-scale or specific sense. Many techniques have emerged to analyze PCR products, with cloning and sequencing for the Sanger sequencing to the next generation sequencing that no-longer requires cloning. Sequencing technologies including pyrosequencing (454), Illumina, Ion Torrent, Pac Bio, MinION differ in their principle, the length of the sequenced fragment and the degree of sequencing errors. Apart sequencing of PCR products gained from nucleic acids extracted from soils (barcoding), so called shotgun sequencing analyze directly DNA extracts from soil and enable assembly of large portions or even whole genomes of soil fungi and ideally to capture the metagenome of soil fungi, i.e., the assembly of all fungal genomes present in a sample. All these technologies require bioinformatics tools to assemble the produced fragments, filter out chimera. By use of reference data banks, such as UNITE (<https://unite.ut.ee/>) and FUNGuild (<http://www.funguild.org/>) sequences can be assigned to taxa and functional ecological guilds. Owing to the power of these techniques, monitoring diversity of soil fungi at global scale has become possible.

Activity

Specific assessment of fungal activity in soils is difficult, since it will invariably occur in combination with the activity of the rest of the biomass (Nannipieri et al., 2017). One approach is to measure bulk respiration in the presence and absence of metabolic inhibitors specific to prokaryotes such as streptomycin; assuming the inhibitors are actually specific and fully effective, the difference in respiration is attributable to fungi. More effective procedures are based on measuring the incorporation of stable or radioactive isotopes into fungal marker compounds, such as the incorporation of ^{14}C -labeled acetate into ergosterol. Since RNA is produced to a greater extent in metabolically active cells and hyphae, analysis of directly extracted RNA, in a similar manner to that used for DNA (see “Physiological and molecular methods” section) offers great potential. Although, RNA is difficult to extract from soils and mycological applications to date have been relatively limited, the era of soil fungal transcriptome and meta-transcriptome analyses is now opened. Fractionation of substrate labeled with stable isotopes (e.g. ^{15}N , ^{13}C , ^{18}O deuterium) enables their breakdown trajectory along soil food webs to be followed, and hence improve understanding of soil microbiome functioning.

Exploitation of soil fungi

Soil fungi are unquestionably vital to the functioning of terrestrial ecosystems but they also play an important and increasing role in biotechnology and environmental management. Culinary exploitation and cultivation has occurred for millennia, with mushroom-growing industries present on most continents. However, in comparison with their species richness, only a minute part of edible and otherwise useful fungi are produced under controlled culture conditions, owing to the complexity of factors that trigger sexual reproduction of mushrooms. As an example, the Perigord truffle (*Tuber melanosporum*) remains resistant to routine, large-scale cultivation and is consequently one of the most expensive epicurean foods on a weight basis, retailing at potentially

thousands of dollars per kilogram. On a contrasting scale, the production of single-cell protein in large-scale fermentors from *Fusarium graminearum* is a successful and established industry. Many fungi isolated from soil provide a range of important primary and secondary metabolites, which are exploited industrially. These include various organic acids (e.g., *Aspergillus*, *Rhizopus* spp.), polysaccharides (e.g., *Aureobasidium* spp.), and lipids (e.g., *Fusarium* spp.), as well as antibiotics (e.g., *Penicillium*, *Aspergillus*, *Sordaria* spp.), other pharmaceuticals (e.g., *Penicillium*, *Tolypocladium* spp.), and agro-chemicals (e.g., *Strobilurus* spp.). Several thousand antibiotics derived from fungi have been identified, but relatively few have found clinical use, since most are too toxic to humans. Fungi that are antagonistic to pathogens (see above) have actual and potential use as biocontrol agents against other fungi, nematodes, and weeds. Establishment of plants in horticultural or restoration scenarios can be compromised by the absence of suitable mycorrhizal hosts; inoculation with appropriate fungal partners can be effective and economically viable. Use of fungi in bioremediation of soils contaminated by industrial pollutants such as phenolics, hydrocarbons, and heavy metals has potential – claims are often made for Basidiomycete species that show strong phenol oxidase activity, such as *Phanerochaete chrysosporium* – and, in combination with plants (phytoremediation), metal-solubilizing fungi may offer effective soil cleanup mechanisms. Increasing use of soil fungi is likely given further research and understanding of the biology of these highly diverse and versatile organisms. However, as mentioned above, survival of fungal inoculates in soils is limited by the mycostasis phenomenon mentioned in the Section “Physiology and reproduction,” which challenge attempts to inoculate favorable fungal single strains or consortia.

Therefore, the greatest actual challenge in research on soil fungi and microbial ecology is to understand the processes of microbiome community assembly and functioning, how they answer to soil use, and how they can be steered by management practices to improve soil sustainability and ecosystem services such as high productivity, carbon storage and resistance to biotic and abiotic stresses. This is the objective of agroecology, which promotes the concept of soil health (Wilhelm et al., 2022).

Abstract

Photosynthetically active prokaryotic cyanobacteria as well as eukaryotic microalgae, including green algae and diatoms frequently colonizing the top soil environment, group as soil algae. This taxonomically diverse group fulfils important ecological functions including carbon and nitrogen fixation, bio-weathering activities and various microbial interactions. In contrast to their aquatic relatives, the ecophysiology of soil algae is highly adapted towards the terrestrial environment that also offers new possibilities for biotechnology.

Key points

- The most important phyla of soil algae include members of Cyanobacteria, green algae and diatoms.
- Soil algae play an important role in nutrient cycles and facilitate microbial interactions within the soil environment.
- As pioneer organisms and ecosystem engineers, they are often the first microbes to colonize new terrain and prime soils.
- In contrast to their aquatic relatives, soil algae possess unique adaptations for life within the soil environment which can also be used in biotechnology.

Introduction

Phototrophic bacteria (Cyanobacteria) and eukaryotes (e.g., green algae), which inhabit terrestrial locations and reproduce sexually, via gametes, or asexually, via viable spores, are grouped as soil algae. They are often also referred to as ‘terrestrial microalgae’. Soil algae occur as unicells or filaments, solitary or aggregated in colonies, as free-living organisms forming biofilms or in symbiotic associations, such as in lichens (Figs. 1 and 2). In addition, they are a frequent constituent of the so-called biological soil crusts (biocrusts) where they—together with lichens, mosses and heterotrophic microbes—colonize the top millimeters of soils. Biocrusts are distributed world-wide. They are particularly well-studied in arid regions such as deserts where soil algae are a main component of biocrusts. The distribution of soil algae takes place via wind, water, soil relocation, human disturbance or via animal transport including cattle or migratory birds.

The cells of soil algae are between 0.5 µm and 40 µm but most of them are about 10 µm in diameter. The most common soil algae are prokaryotic Cyanobacteria as well as eukaryotic green algae and diatoms (Fig. 1, Table 1). Cyanobacteria appear

Fig. 1 Simplified taxonomic key to the most common types of soil algae. Depicted are prokaryotic filamentous Nostoclean cyanobacteria with heterocytes (e.g., *Scytonema*), cyanobacteria of non-heterocytous orders (e.g., filamentous *Oscillatoria*, unicellular *Synechococcus*, unicellular *Gloeocapsa* with layered mucilaginous sheath, aggregated *Chroococcus* colony with mucilaginous sheath). Eukaryotic Chlorophytes and Streptophytes (e.g., multi-branched macroscopic *Chara*, unicellular *Trebouxia* with a pyrenoid in the lobed chloroplast, unicellular *Chlamydomonas* with flagella, filamentous *Klebsormidium* with parietal chloroplasts). Xanthophytes (e.g., filamentous *Vaucheria* with multiple chloroplasts). Diatoms of the bilaterally symmetric pennate and radially symmetric centric type, both with their glass-like cell wall (frustule) consisting of an upper (epitheca) and bottom box (hypotheca).

blue-greenish because of their special pigments phycoerythrin (red) and phycocyanin (blue) that mask the chlorophylls. Their cells can be surrounded by a thick mucilaginous sheath made of extracellular polymeric substances (EPS) that contains sugars but also proteins. Eukaryotic green algae on the other hand are surrounded by a cellulose-rich cell wall and contain at least one chloroplast with a light greenish color reflecting chlorophylls as their main photosynthetic pigments. Diatoms are remarkably diverse due to a high variability of their characteristic structured silica cell wall and appear brownish due to fucoxanthin as their dominant pigment.

Most soil algae have a photo-litho-autotrophic metabolism, are able to perform oxygenic photosynthesis and are poikilohydric. This means that they are highly dependent on the water availability of their environment as they possess only limited mechanisms to maintain cell turgidity. Besides liquid water from, e.g., rain, they can use relative air humidity, fog and dew for photosynthesis. As such they are organisms, predestined to inhabit soils and unweathered rocks, and are regarded as pioneers. They can outcompete higher plants and mosses under certain circumstances such as when the water availability drops below a certain limit.

Due to their ability to fix atmospheric carbon dioxide (CO_2) they play an important role in the carbon (C) cycle. Further, some Cyanobacteria can fix atmospheric nitrogen (N_2) or are reported to mobilize soil phosphorus (P), thus also representing an essential part in the N and P cycles. This means that soil algae are often the first organisms that colonize barren ground and prime this material by an enrichment in C, N and other substances essential for life throughout trophic levels. Soil algae often intimately interact with other microbes such as (lichen-forming) fungi and heterotrophic bacteria and also interact with each other in multipurpose ways. This does not only include symbiotic or parasitic relationships but is most often also important for whole ecosystem functions from the micro- to the macro scale.

Starting in the early 19th century, soil algae were included in plant taxonomic studies before lists of soil algae were compiled in the 20th century for many parts of the world. Nowadays much attention is also paid to soil algae in soil ecological studies and to their role in soil fertility, soil stabilization, pest control, and biotechnology.

Organisms

Prokaryotic algae

As one of the oldest forms of life, Cyanobacteria are prokaryotic cells which do not contain any nucleus but free DNA and 70S ribosomes in the cytoplasm (Table 1). They are Gram-negative bacteria without any flagellum. Oxygenic photosynthesis is performed in variously shaped thylakoids which always contain chlorophyll *a* and additionally may contain chlorophyll *d* and *f* which absorb light in the far red. The accessory pigments, the so called phycobilins, phycocyanin (blue) and phycoerythrin (red)

are organized in phycobilisomes. They allow photosynthesis also to take place under low light conditions by exploiting the so called 'green gap' in the light spectrum. Due to the proportions of all pigments the color of Cyanobacteria can range from violet (e.g., low-light conditions) to black (e.g., high-light conditions), but most of them appear blue-greenish. Cyanobacteria fix atmospheric CO_2 within polyhedral structures the so called carboxysomes. At these sites the CO_2 concentrating mechanism (CCM) is located so that the enzyme ribulose-1,5-bisphosphate-carboxylase-oxygenase (RuBisCO) can operate in an elevated CO_2 atmosphere that makes the C-fixation more efficient. Nonetheless, most of them are also facultative photoheterotrophs taking up compounds including glucose, fructose, pyruvate, acetate and some amino acids. Prominent storage compounds of Cyanobacteria encompass cyanophycin starch which is similar to glycogen, cyanophycin (an arginine- and asparagine polymer), and volutin (a polyphosphate). For example, above an internal P concentration of about 0.7% dry weight, granules of polyphosphate start to form in *Nostoc*.

The cell size of cyanobacteria varies between 0.5 μm and 40 μm . They occur as single cells, as cell colonies or filaments (Figs. 1 and 2). The filaments can be either unbranched or truly or untruly branched including various special types. Some species show cell differentiation. For example, in one of the soil-ecologically most important orders, the Nostocales, vegetative cells, akinetes and heterocytes (formally known as heterocysts) exist. Heterocytes are specialized in N_2 fixation. They contain the enzyme complex nitrogenase, an Fe—S—Mo containing enzyme which is only active if no other N-source such as nitrate (NO_3^-) is available and no oxygen (O_2) is present. For these reasons the heterocytes are enclosed by a thick cell wall. The nitrogenase reduces N_2 to ammonia (NH_3). On the other hand, akinetes are resting cells which are rich in storage compounds.

Table 1 Selected soil algae with a common world-wide distribution.

Domain	Phylum	Class	Traditional name	Common terrestrial species	Habitats
Bacteria	Cyanobacteria	Cyanophyceae	Blue-green algae	<i>Nostoc commune</i>	Soils, lichen photobiont

Cyanobacteria only reproduce asexually by, e.g., fragmentation of filaments (development of hormogonia) (Fig. 2). Cyanobacterial cells may produce EPS such as polysaccharides and polypeptides (Fig. 1). They can form jelly sheaths which protect cells from rapid dehydration and enhance quick re-hydration. Further, substances such as gloeocapsin or scytonemin can be placed into the EPS which protects the cells from high UV radiance. The EPS layer can also be used as a short-termed storage for proteins and other substances that can later be re-absorbed. This is often the case when the C:N ratio in the cells is outbalanced e.g., during dehydration events.

The taxonomy of microalgae, including terrestrial Cyanobacteria, is under constant revision. The class Cyanophyceae, formally also known as blue-green algae, includes eight orders (Table 1). One of the most important orders of the terrestrial Cyanophyceae is the Nostocales. Here, one of the most common representatives is the taxonomically diverse genus *Nostoc* that can be found in soils world-wide including hot and cold deserts. *Nostoc* is a filamentous genus with rounded cells and mostly coiled arrangement encapsulated by a wide EPS sheath (Fig. 2). The colonies mainly form biofilms or rounded thalli that mostly reach macroscopic size due to the massive amounts of EPS material. They form heterocytes for N₂ fixation, akinetes as resting stages and have a complex life cycle that often mimics the forms and shapes of other cyanobacterial genera including motile hormogonia. The genus *Nostoc* is a major player in biocrusts where it fulfils a variety of ecosystem services including N₂-fixation and prevention of soil erosion. Further, it can be the photosynthetic symbiont in lichens or plant roots (Cycads). In biotechnology it is used for EPS production in the cosmetic industry, for pigment extraction (phycocyanin) in the food industry (food dye), and for waste-water treatment due to its toxins absorbing abilities.

Eukaryotic micro-algae

Eukaryotic soil algae are characterized by a cell structure that includes a DNA-containing nucleus, 80S ribosomes and mitochondria in the cytoplasm as well as a cell wall made up from pectin in fibrillary base structure of cellulose, xylans, and mannans (Fig. 1). The cell wall can be encrusted by silica (SiO₂), as in the algal class of Bacillariophyceae, also called diatoms (Table 1). Chloroplasts of the micro-eukaryotic algae are made up of at least two membranes and contain free chloroplast DNA and 70S ribosomes (endosymbiotic theory NOTEREF _Ref111579902 ¶ 1). The chloroplasts contain thylakoids with photosystems II and I located in the thylakoid membranes. The photosystems are made up of accessory pigments such as carotenoids or xanthophylls as well as of chlorophyll *a + b* (phylum Chlorophyta) or *a + c* (phyla Xanthophyta, Bacillariophyta), a reaction center (protein complex P680, P700) and a water-splitting complex. Eukaryotic soil algae build up starch via the Calvin cycle. At species-specific pyrenoids, a structurally

NOTEREF _Ref111579902 ¶ 1 The endosymbiotic theory proposes that organelles, such as mitochondria and chloroplasts found in eukaryotic cells were once independent prokaryotic microbes.

identifiable round complex often in the center of the chloroplast(s) of some green algae, the CO₂ concentrating mechanism takes place so that RuBisCO can operate more efficiently. The number of the chloroplasts per cell are species specific. Many Chlorophyta and Xanthophyta are facultative chemoheterotrophs which shows the potential for growth of these algae beneath the soil surface.

In contrast to Cyanobacteria, eukaryotic soil algae reproduce asexually by disintegration of filaments, or binary fission, as well as sexually by the development of zoospores with or without two flagella. Due to these flagella, eukaryotic soil algae are able to move actively and redistribute in water films that form within the porous space of soil particles.

Within the Plant kingdom terrestrial eukaryotic algae mainly group into the phyla Chlorophyta (classes Chlorophyceae (green algae), Trebouxiophyceae), Streptophyta (class Klebsormidiophyceae), Xanthophyta (class Xanthophyceae) and Bacillariophyta (class Bacillariophyceae) (Table 1). Chlorophyta are mainly free living or occur as symbiotic partner in biocrusts and lichens. They contain chlorophyll *a + b*. Klebsormidiophyceae are known to integrate soil particles due to their filamentous habitus. They can also stick particles together due to EPS production. Xanthophyceae, traditionally known as yellow-green algae, contain chlorophyll *a + c*, β -carotene and xanthophyll but no fucoxanthin, whereas Bacillariophyceae, also known as diatoms, also contain fucoxanthin which covers the chlorophyll *a + c* so that plastids appear brownish. Bacillariophyta can be up to several hundred μm in size. Their cell wall (frustule) is box-like, consisting of an upper (epitheca) and bottom box (hypotheca) part. They are either bilaterally (pennate type) or radially symmetric (centric type).

One of the most abundant green algae are members of the genus *Chlorella* which belong to the class Trebouxiophyceae of the phylum Chlorophyta (Table 1). Their cells are small, usually between 2 μm and 10 μm . They have a light green color and contain one chloroplast that often fills half the cell. They grow quickly in nature and especially in the lab where they form slimy, light green biofilms in which their cells mostly do not aggregate. The cell content is rich in lipids and also proteins which makes *Chlorella* the most used alga in commercial biotechnology. Dried and pressed into pills it is often sold as a food supplement. *Chlorella* is mostly grown in open-pond systems or closed bioreactors comprising hundreds of liters. In those, it gains biomass very quickly and also has been a promising candidate to generate bio-fuel.

Identification of soil algae

Soil algae growth can be directly examined in soil by microscopic techniques. For an exact determination of species, however, algae are extracted from soil by, e.g., soil-water suspensions. Subsequently, soil algae are cultured in liquid media or are grown on agar plates. Only organisms of axenic or at least unialgal cultures are then identified at a species level using microscopy and literature keys.

Cultured soil algae can also be examined by genetic approaches. A polyphasic approach using microscopic as well as genetic techniques produces the most reliable results and reflects the scientific state of the art. In this approach, group-specific primers are used to amplify and subsequently sequence specific gene regions, on which the scientific community has agreed as valid reference points. Bioinformatic analyses such as phylogenetic tree reconstructions of these single or multi locus gene regions are then subjected to statistical methods that generate the relatedness of strains compared to DNA information from other species and strains. Describing new species follows detailed international rules and keys. Cultured species that were examined by this approach are finally transferred to public culture collections that maintain the curation of these strains and make them publicly available for the international scientific community. In some cases, phylogenetic constructions of one or even several sequenced gene regions do not create sufficient information to properly determine the taxonomic position of a strain. In such a case, full genome sequencing is an approach that accesses the full DNA information of a single organism as the *ultima ratio*. This technique becomes more and more affordable and offers new possibilities, such as genome mining approaches, in which the genetic information is systematically screened for the potential abilities to produce natural products for human use, such as antibiotics.

Habitat effects on soil algae

Algal distribution in the soil profile

On average, $(5.5 \pm 3.4) \times 10^6$ soil algae inhabit each gram of Earth's surface soil with particularly high abundances in acidic, moist and vegetated soils. They mainly dwell in the upper few millimeters of the terrestrial soil where there is sufficient light to perform photosynthesis. Some soil algae have developed strategies to deal with high light conditions, such as in vegetation-free soils. Here, they slide, for example, on their EPS matrix a few millimeters below the soil surface. Depending on the soil texture as well as on the moisture content of the soil and thus penetration of light, their occurrence is usually limited to the upper millimeters (in fine soils) or centimeters (in coarse soils) of the soil. However, cracks in dry soil may be considerably deeper and due to the downward-movement of water, agricultural activity, root growth or soil faunal activity, soil algae have also been found at depths to two meters. Thereby, their abundance decreases with increasing soil depth. At lower soil depths, cells are mainly inactive and in resting stages.

Habitat niches

Generally, five different lifestyles can be distinguished for soil algae: they can live either edaphically (in or on the soil), *endo*- or *hypolithically* (in or beneath stones), *chasmoendolithically* (in cracks of stones and rocks), *epilithically* (on top of rocks), and symbiotically as, e.g., photobiont partner in lichens. Depending on their habitat niche they encounter different environmental

conditions due to variation in factors such as solar radiation, temperature, water and nutrient availability or pH value. These factors shape their preferential niche and affect soil algal species richness and diversity and subsequently the ecosystem services that they can provide.

Effect of solar radiation on soil algae

The solar radiation reaching Earth's surface consists of 8% ultraviolet (UV), 42.3% visible (VIS) and 49.4% infrared (IR) radiation. As such it is an important environmental factor for algal distribution within the soil profile, for differentiation of soil algal cells as well as for regulation of sex and zoosporegenesis in eukaryotic soil algae. Due to a variety of tolerance mechanisms including the activation of several photo/dark repair mechanisms, antioxidant systems and the biosynthesis of UV-photoprotectants (e.g., mycosporine-like amino acids, scytonemin, carotenoids, polyamines), soil algae are very resilient to high UV radiation stress.

Depending on their chlorophyll type and accessory pigment setting, soil algae can use visible and infrared light with absorption maxima ranging between 430 nm and 710 nm wavelength for photosynthesis. Generally, visible light penetration of soil is stronger at longer wavelengths and deeper in wet soil compared with dry soil, thus creating distinct habitats for soil algae. Cyanobacteria, especially those containing chlorophyll *d* or *f*, can make use of the very low light conditions that occur further down the soil profile, within gypsum blocks or even in almost dark caves. In addition, and similar to other phototrophs, Cyanobacteria can regulate functions of light-harvesting antennas in response to changes in the environment, such as the spectral composition and intensity of light or temperature amplitude.

Infrared radiation affects soil surface temperature and depends on soil moisture thus, directly affecting soil algae in the upper few mm of the soil. Here, algal activity is governed by the range and fluctuation of temperature. Soil algae are extremely resistant to low temperatures and are even found in the Arctic and Antarctic regions where they can show metabolic activity below the freezing point. Also, soil algae such as *Microcoleus vaginatus* can tolerate high temperature peaks of around 110 °C.

Soil algae have developed several strategies to cope with high radiation. Some invest in the ability to move, so that they can glide into deeper soil layers. Others, rather than invest in motility, produce UV protection pigments. In addition, the symbiosis with lichen-forming fungi also can be found for some cyanobacteria and green algae. In this association, the fungal partner (mycobiont) produces pigments to protect the algal photobiont from harmful radiation. In arid deserts with high radiation, some types of soil algae prefer a hypolithic lifestyle in which they grow on the ventral site of quartz stones. These stones are whitish and remain cooler compared to their surrounding which supports water condensation on their surfaces. In addition, the translucent stones filter harsh UV radiation but at the same time allow visible radiation to penetrate which is sufficient for photosynthesis (also referred to as 'microbial cabana hypothesis').

Effect of soil moisture on soil algae

The moisture status of the soil is of great importance for soil algal growth. It ensures physiological functionality of the organisms including photosynthesis, is essential for nutrient availability and affects O₂ level as well as light and heat travel in soil. Most soil algae are poikilohydric organisms showing equilibration to ambient humidity and rapid responses upon water gain. However, both Bacillariophyceae and Xanthophyceae are very susceptible to desiccation. Some of them even depend on inhabiting very wet soil (*Botrydium* sp.) or salt marshes (*Vaucheria* sp.). A low redox potential of waterlogged soils can also lead to increased growth and enhanced N₂ fixation by cyanobacteria. For other soil algae, too much water can be harmful as the water film surrounding the cells acts as a diffusion barrier that slows down O₂ and CO₂ gas exchange thus, leading to an inhibited or reduced photosynthesis. Bacillariophyceae, for example, exhibit vertical movement within biocrusts in response to light and water availability. Many cyanobacteria are even well adapted to limited water availability. They are abundant in arid regions where they are able to maintain metabolic functions using water from dew. Green algae can also use high relative air humidity above 90% for their photosynthetic activity but also runoff water from trees (stem flow) or stones can be a sufficient water source. As an integral part of biocrusts, some soil algal communities have also been reported to decrease in their abundance and to alter their community composition under frequent wet-dry cycles.

Effect of soil pH and nutrient availability on soil algae

Soil pH is a controlling factor of the abundance and diversity of algal communities. While Cyanophyceae as well as Bacillariophyceae predominate in alkaline soils, Chlorophyceae can mainly be found in acid soil. However, soil algae can also actively change the pH of their micro-environment by mediating bio-weathering activities. Both effects, alkalinolysis and acidolysis have been reported by different soil algae that etch their substrate during nutrient acquisition.

The addition of inorganic nutrients such as available N or P can suppress algal growth but has also been found to increase algal diversity. Most algae react sensitively to increasing N to the levels at which their species richness often declines. For these reasons agricultural areas are mostly free of cyanobacteria but can be strongly colonized at least temporarily by green algae.

Although micro-habitat preferences have been observed for xeric algae either on, under, or within rock, gravel, and diaphanous substrates, little is known about the influence of soil texture on algal distribution. However, the texture of mineral soils has been stressed as an important factor for determining distribution of diatoms and cyanobacteria as it influences light, heat, water retention and infiltration rate.

Algae as soil conditioners

Free-living or symbiotically associated soil algae occur on and within rocks, gravel and stones where their biogenic weathering activities contribute to the disintegration of the solid substrate. These processes include physical impacts as a result of, e.g., swelling and shrinking of cells due to cell turgor changes. Further, chemical processes mediated by soil algae such as alkalization and acidification impact on the substrate. Over geological timescales, these processes contribute to the formation of a young soil, e.g., a terrestrial protopedon in the Southern Atacama Desert.

As primary producers, soil algae play an important role in the colonization of barren soils and their soil conditioning effects on soils, including agriculturally used soils, has been recognized. They improve the soil's C content by photosynthetic production of organic matter. Especially the production of EPS can aggregate soil particles thus, improving soil structure and preventing soil erosion by wind and water. Particularly the formation of biocrusts by diverse microbial communities is very successful in this respect. For example, desertification can be actively stopped by raising specific soil algae in the lab and re-introducing them into desert areas where they can stabilize the top soil layer and prevent further erosion or desertification. An increase in soil organic matter also has positive effects on soil water retention and water holding capacity. Further, soil algae can improve edaphic biomass and activity as they function as food for many soil organisms. Turnover and leakage by soil algae release nutrients, permanently but slowly, and makes them a welcome reservoir also for plant nutrients. Further, phytohormones produced by soil algae can stimulate plant (root) growth. Their metabolites are also known to contribute to phytopathogen and pest control. In addition to the above-mentioned positive effects by both, Cyanobacteria as well as eukaryotic soil algae, only the former can further condition soil N content by fixing atmospheric N₂. Cyanobacteria are also known to increase plant available P by solubilizing immobile P and can develop close association with roots. All of the effects mediated by soil algae have been shown to improve plant performance, including germination, N- and P-uptake, plant height and weight as well as crop yield.

Soil algae in nutrient cycles

Macronutrient cycling

The role in the C cycle

Soil algae play a pivotal role as primary producers in the carbon cycle. In the process of photosynthesis, they convert atmospheric carbon dioxide and water into oxygen and glucose (Eq. 1). For this process light energy is required.

Globally, soil algae take up around 3.6 Pg C per year. This relates to about 6% of the net primary production of the terrestrial vegetation. Within the soil, they thus contribute to the global soil organic matter pool of 2400 Gt C. Within the algal cells, glucose is converted to many different organic compounds which are vital for any functioning cell. Once in soil due to algal release of certain compounds (e.g., EPS, enzymes), leakage from algal cells or after algal cell death, organic compounds are available to all soil organisms. Eventually, any C-containing compound is mineralized again to CO₂ and water (H₂O) by soil microorganisms and the C-cycle can start again.

The role in the N cycle

In addition to carbon, some Cyanobacteria can also fix atmospheric N₂. This N fixation is vital for the replenishment of the soil N pool which provides the most important N supply for all other terrestrial auto- and heterotrophs. Globally, atmospheric N-fixation by cryptogams, of which soil algae are part of, amounts to about 49 Tg N per year, which corresponds to 46% of the total biological N fixation. Due to their nitrogenase complex, about 15% of all prokaryotes can convert N₂ to NH₃, a process which is very energy consuming (adenosine triphosphate (ATP)-expensive) (Eq. 2). Finally, ammonium (NH₄⁺; equilibration result of NH₃ in water) and α-ketoglutarate react with glutamate, an amino acid which is used in protein biosynthesis.

The NH₄⁺ or organically bound N is then released from the cyanobacterial cell into the soil from where it subsequently can be taken up by plants and heterotrophic soil microorganisms. In symbioses of cyanobacteria with plants or fungi (e.g., *Azolla*, *Gunnera*, Cycads, lichens) the ways of N-loss are minimized by intimate associations of the two partners. Only anaerobic denitrification products and NH₃ losses from soil replenish the atmospheric N pool.

The role in the P cycle

Soil algae can solubilize immobilized phosphorus (P) thus, essentially contributing to the P-availability in soils. Given that most organisms can only take up soluble P (PO₄³⁻, HPO₄²⁻ or H₂PO₄⁻), solubilization of P from insoluble P forms, such as primary minerals (apatites), secondary minerals (Ca, Fe, Al, Mn phosphates), sorbed P (onto clays and Al, Fe oxides) or organic compounds (e.g., phytate), is an important step in the P-cycle. P mobilization by soil algae can take place by acidification, enzymatic cleavage or chelation.

Acidification results from respiration (respired CO_2 reacts with H_2O of the soil solution to H_2CO_3), production of NH_4^+ or excretion of organic acids. For example, under low pH, P from e.g., hydroxyapatite can be set free from the crystal lattice according to Eq. (3). Also, carbonate-bound P is freed by a decrease in soil pH.

Further, to solubilize P, soil algae can produce and release phosphatases. Most cyanobacteria, green algae and lichens have phosphatases in their cell walls and mucilaginous sheaths. These extracellularly working enzymes hydrolyze organic phosphates thus, liberating P from organic compounds such as inositol phosphates or sugar phosphates. The most intensively investigated phosphatases belong to the group of either phosphomonoesterases or phosphodiesterases. Phosphomonoesterases are further classified according to their pH optima as alkaline or acid phosphatases. Phosphatase expression is mainly substrate induced. In the case of phosphomonoesterase, activity is inhibited by the hydrolytic product phosphate. Cyanobacteria, however, may respond to internal P concentrations rather than external phosphate concentrations.

Cyanobacteria can also produce chelators to solubilize P. Metal chelators such as siderochromes thereby complex Ca, Al, and Fe to release P originally bound by these metals. Also, other water-soluble substances such as peptide-N or riboflavin can be secreted.

Micronutrient cycling

Soil algae are not just vital for the macronutrient cycles of C, N and P but also play a role in micronutrient cycling. Commonly, micronutrients are metal constituents of enzymes mediating biochemical reactions. This includes reactions such as those in the photosynthetic process, the respiratory chain or the nitrogenase complex for N fixation. For soil algal growth, elements such as Fe, Mn, Cu, Zn, Mo, V, B, Cl, Co and Si are essential at concentrations below 10^{-5} M and are added as micronutrient solutions to culture media in the lab. The most commonly used culture media (including various adaptations) for green algae is Bold's Basal Medium (BBM) and that for Cyanobacteria is BG 11. Soil algae are able to mobilize those micronutrients from soil, take them up and accumulate them within their biomass. Excreted chelators may help in the process of mobilization. Once in a soluble state these micronutrients can also be taken up by other organisms. As such, soil algae growth can contribute to an increased supply of micronutrients for other organisms including crop plants and can even influence plant properties such as taste and aroma or the ability of plants to withstand drought periods. The accumulation of micronutrients within soil algal biomass further provides a high amount of these nutrients to the soil after soil algal death.

Biotic interactions of soil algae

As primary producers, soil algae convert atmospheric CO_2 into glucose and from there also into other organic carbon compounds. Hence, they are an important carbon source for many heterotrophic soil organisms including protozoa, tardigrade, earthworms or isopods which feed on living algae. If not eaten, they represent a reservoir for carbon but also inorganic nutrients before they function as a food for those organisms which live on compounds released from dead organic matter.

Soil algae are also known to be partners in a facultative mutualistic symbiosis. Cyanobacteria *Nostoc* sp. and *Anabaena azollae*, both of which can fix atmospheric N_2 in heterocytes, live in close association with plants. While *Nostoc* sp. can be found in the roots of Cycads or the rhizome of *Gunnera* sp., *Anabaena* sp. resides in leaf cavities of the freshwater fern *Azolla* sp. Here, they provide N as amino acids and extracellular NH_3 to the plant. In the fast-growing *Azolla* fern, *Anabaena azollae* may fix up to about $2 \text{ kg N ha}^{-1} \text{ day}^{-1}$ thus making *Azolla* application a good practice for sustaining soil fertility and crop productivity in paddy rice cultivation worldwide.

In the obligate mutualistic symbiosis of lichens, soil algae represent the photobiont which is closely associated with the fungal mycobiont. The mycobiont forms a thallus in which the photobiont is concentrated within an algal layer or algal stacks (heteromorous thallus) or is irregularly distributed within the whole thallus (homoimorous thallus). Photobiont species belong either to the phyla Cyanophyta or Chlorophyta. Of all known lichens, about 10% are cyanobacterial lichens (cyanolichens) with *Nostoc* sp. as the predominate photobiont. In green algae lichens (chlorolichens), 24 different genera may act as photobiont but *Trebouxia* sp. occurs in more than 75% of all green algal lichens. Both types of photobionts provide sugars for the mycobiont. Cyanobacteria, in addition, provide N in some cases. The mycobiont is one of about 13,500 species belonging to either the ascomycetes (predominating) or basidiomycetes. It protects the photobiont from desiccation and strong UV radiation, improves its P supply and offers a joint reproduction strategy. Generally, in lichen symbiosis, photobionts reproduce only asexually while mycobionts reproduce asexually as well as sexually. The meiospores are produced within apothecia which often are characteristic structures of conspicuous character on the lichen thallus. For simultaneous reproduction of photo- and mycobiont, special reproduction organs are formed by the lichen. Isidia are outgrowths which get distributed by wind and water after easy separation at a breaking point. Soralia on the other hand are breakup regions. Both structures are made of fungal hyphae wrapped around photobiont cells which act as propagules and regrow full lichens under adequate conditions.

As free-living organisms or as part of lichens, soil algae can be observed in biocrusts. In these associations they play the role of primary producers which are tightly associated with heterotrophic organisms as well as their byproducts in the upper few mm of soil. A characteristic biocrust type has been detected in the Atacama Desert. Here, up to 80% of ~ 0.6 cm grit stones are colonized by a diverse lichen community which even concatenate these grit stones. Biocrusts can also be found on ice free areas of the Arctic and Antarctica.

Outlook

Using microalgae in biotechnology, offers innovative solutions to meet the growing demand for bioactive ingredients, food and feedstock with low resource consumption. To date, however, limitations in physiology and bioreactor design have prevented an economically feasible transfer of numerous microalgae-based production processes into an industrial scale. Soil algae are especially interesting for their biotechnological potential due to their low maintenance and useful properties. The previous focus on aquatic microalgae for biotechnological approaches might be due to the fact that they are highly abundant in freshwater and marine habitats displaying the main driver of aquatic primary production. Moreover, they are—at the first glance—easy to cultivate in liquid cultures. The outstanding role of terrestrial microalgae, e.g., in nutrient-limited ecosystems as soil stabilizer and N supplier, was only recognized three decades ago. Compared to aquatic strains, soil algae can be grown under low light conditions, ambient air temperature and low nutrient concentrations. In addition, high value products such as pigments can easily be concentrated in soil algae once stressed by short-term high-light exposure. The high content of proteins and lipids of soil algae will be a commercial factor influencing the future agronomical systems.

Due to the adaptability of cyanobacteria, astrobiologists are drawn to the idea that cyanobacteria could be used to terraform Mars. Terraforming is defined as a process of planetary engineering, specifically directed at enhancing the capacity of an extra-terrestrial planetary environment to support life including that of human beings. Based on data collected so far, Mars is fairly different from Earth but remains the same in a few key characteristics. While some climatic parameters are comparable and atmospheric composition, and surface pressure are relatively similar to Earth, Mars has lower gravity, lower average sunlight and longer years/seasons compared to Earth. Hence, Earth's soil algae may contribute to terraforming Mars given that they are able to inhabit also low light environments and can cope with long dry periods.

In summary, the microbial world of soil algae at our feet is often overlooked but significantly contributes to major global processes from the micro- to the macro scale and holds a great potential for biotechnology and human use.

Abstract

This chapter is a synopsis of the soil arthropods that which exist in soil and its associated organic litter layers and form part of the detrital food web. The arachnids include mites, spiders, harvestmen and pseudoscorpions; the hexapod classes are Protura, Collembola, Diplura and Insecta; crustaceans are represented by the pillbugs; and the myriapods consist of centipedes, millipedes, pauropods and symphylans. Each taxon is a separate and distinct entity, not like any of the others and deserving of study. Phoresy by mites is covered, as are the myriad approaches some arthropods take to avoid being noticed by a predator.

Glossary

Basal hexapod An informal grouping of three separate classes of six-legged non-insect arthropods (Protura, Collembola, Diplura) plus two orders of true insects (Archaeognatha, Zygentoma). The five taxa are distinctive in never having had winged ancestors, unlike all the other insects. "Apterygota" is an increasingly obsolete term for these arthropods.

Batesian mimicry Protective mimicry in which a harmless species has evolved to resemble the appearance of a harmful or more dangerous species. Counterpart to Müllerian mimicry.

Clade A grouping of related taxa based on phylogenetic analysis. The taxon level can be at any level from species to phylum.

Class The first major taxonomic division below phylum. In this paper, several classes of the phylum Arthropoda are discussed.

Müllerian mimicry Protective mimicry in which two or more unrelated species with similar noxious or unpleasant defenses develop similar appearances. Often contrasted with Batesian mimicry.

Phoresy A dispersal behavior of many invertebrates, especially larval mites and pseudoscorpions, in which they cling or attach usually to a larger arthropod for transport to new localities or food sources.

Sympatry The condition of organisms living together in the same place at the same time. Usually applied to related species living and presumably interacting in the same restricted area but using available resources somewhat differently. The opposite term is allopatry.

Key points

- Soil arthropods form an important part of the detrital and grazing food webs, deconstructing organic matter so that it can eventually be recycled into nutrients usable by photoautotrophs, especially plants.
- The soil arthropod "universe" comprises a full range of detritivores, predators and parasites with innumerable interactions that keep undisturbed systems in balance.
- Mites (Acari) are by far the most abundant and diverse soil arthropods, followed by Collembola (springtails). Spiders and beetles are their most significant predators, but many other smaller taxa, such as centipedes, are effective predators as well.
- Evolution has produced a dizzying array of morphological, behavioral and reproductive specializations to enhance the survival of each species.
- Camouflaged appearance, mimicry of stinging insects and production of noxious exudates are important means by which many soil arthropods protect themselves.

Introduction

The forces of gravity and weather sooner or later bring terrestrial life back to earth as dead organic matter. This dead matter provides the energy to drive the detrital food web (DWB), the components of which include nearly every class and order of invertebrates. At the same time, the grazing food web, which we usually think of as above the soil surface, is active on plant roots and other subterranean plant parts (e.g., plant-parasitic nematodes, cicada nymphs, beetle larvae). These grazing organisms eventually die and thus become incorporated themselves into the DWB. The ultimate function of the detrital food web is to break down complex organic materials into nutrients that can be used by photosynthetic organisms (photoautotrophs), which thus drives the maintenance of terrestrial life on the planet.

The DWB operates in the zone between bedrock and the surface, where organic material is present for degradation. Organisms of the DWB typically are absent from deep soil layers that contain little organic matter. In general, most decomposition occurs in the top meter of soil where most of the organic matter resides. Much of this decomposition is fostered, especially in its early stages, by arthropods living in this soil depth.

From Eisenbeis G and Wichard W (1987) *Atlas on the Biology of Soil Arthropods*. Springer-Verlag: Berlin. 437 pp; Chapin FS III, Matson PA and Vitousek PM (2011) *Principles of Terrestrial Ecosystem Ecology*, 2nd edn. Springer: New York. 529 pp.

The differentiation of organisms strictly associated with soil from those in detrital layers covering the soil surface may be difficult since movement between the layers is common and sometimes both layers are necessary for life cycles to be completed. The soil profile conventionally is divided into four horizons: O (organic), A (surface), B (subsoil) and C (substratum). The O-horizon, in turn, is expansively refined (Table 1) by sublayers, which are important because the size and connectivity of the pores within, help determine the distribution and movement of soil fauna in the organic horizon. Roots, the channels left after roots die, earthworm and arthropod tunnels and vertebrate nests also are significant means allowing non-burrowers to move about more efficiently.

Arthropoda is the largest phylum of animals, differentiated by possession of an exoskeleton and jointed appendages. Its major classes are Arachnida (primarily mites, spiders, scorpions), Crustacea (copepods, crabs, lobsters, woodlice), Hexapoda (basal hexapods, true insects) and Myriapoda (millipedes, centipedes). Soil arthropods comprise those members of the phylum that spend a significant amount of their time living in or actively modifying the micro-environment of their soil or detrital habitat. Every extant terrestrial arthropod class has soil-dwelling members (Table 2) and nearly every order of insects has members adapted to life in the soil in at least one stage; even in Lepidoptera (moths and butterflies) some larvae live in the organic layers and many species pupate in soil. Ants and termites are major players in soil turnover and nutrient cycling (along with earthworms), but they will be mentioned only incidentally in relation to other groups as there is a large literature devoted to them. This chapter is focused mainly on the many non-insect arthropods that occupy every nook and cranny of the strata under our feet (Figs. 1 and 3). Short synopses are provided for each order within the groups of soil arthropods that are covered, together with numerous original images to interest and inform the reader. Further Reading may be consulted for additional sources and web sites, respectively.

Detrital food webs and functional groups

The DWB comprises all of the organisms, from prokaryotes to the annelids and arthropods, that contribute to the reduction of organic matter to a state where its basic constituents can be reabsorbed by plants. This process mineralizes carbon and releases nutrients that are utilizable by autotrophs (Potapov et al. 2022). The species richness of organisms in soil is enormous, albeit imperfectly known, but richness is a critical factor in ecosystem functioning, as . . . "environmental heterogeneity strengthens the relationship between biodiversity and ecosystem functioning. . . ." (Albrecht et al. 2021). This result highlights the importance of species assembling into groups of organisms doing similar activities with similar results. Organisms in soil environments have been grouped into a small number of functional groups whose ecological niche dimensions vary from group to group. The application of molecular techniques has revealed numerous species complexes that enhance the understanding of functional group effects.

Fig. 2 Think small! The litter/soil layers contain the some of the smallest known insects (length in mm). A–C, featherwing beetles (Ptiliidae). (A) *Ptinella* sp., a wingless species (0.9). (B and C) Folded and extended wings of winged species. (D) A hister beetle (0.8) (Histeridae). (E) Two wingless scelionid wasp females, *Baeus* spp. (Scelionidae). (F and G), Wingless female flies. (F) Sciaridae (1.6). (G) Phoridae (1.2). (H) Thrips (1.8) (Thysanoptera).

Fig. 3 (A) Typical Tullgren funnel extraction from a mixed deciduous forest. The beetle at lower left is a ptilodactylid; two centipedes are present; the large springtail in the lower center is a *Pogonognathellus* sp. (Tomoceridae); most of the white individuals are onychiurid springtails, the light violet ones are mostly Isotomidae; and the many shiny brown specimens are oribatid mites. (B) An extraction of mites, with several orders represented.

Collecting soil arthropods

"If you don't look, you'll never find anything." — Gary J. Phillips (2014).

Soil arthropods can be collected using several methods, the choice of which depends on the type of investigation and the expected sizes of the organisms (Fig. 2). Tullgren funnels and pitfall traps are two standard approaches but by no means the only ones. Many entomology texts provide descriptions of methodologies and should be consulted for more extensive descriptions (Fig. 3).

The Tullgren funnel (Fig. 4A and B, a modification of the Berlese funnel) uses light and heat from a low-wattage incandescent bulb to drive organisms downward through the substrate placed on the screen. Fleeing arthropods fall through the screen into a container of preservative (usually ethanol) or a culture chamber. The volume or mass of substrate can be measured in advance to provide quantifiable estimates of arthropod density. The unit in Fig. 4 uses a small 15-watt bulb over a 20-cm-diam #4 sieve (4.75-mm apertures). Specimens fall directly into 70–95% ethanol. Isopropanol can be used, as well, at a pinch. Both compounds are suitable for DNA preservation. Typically, there is no need for a surfactant; after the container is capped it can be inverted a few times to wet any floating specimens so that they sink to the bottom. This kind of Tullgren funnel is most suitable for the organic horizons. Mineral soils can be more efficiently extracted by using a finer-meshed sieve or laying a piece of window screen in the sieve. A more elegant and efficient modification of the Tullgren funnel for soil is the high-gradient extractor.

Pitfall traps (Fig. 4C and D) are widely used for soil arthropod surveys. A cylinder of soil is removed with a bulb planter or dug with a trowel to allow the insertion of a cup flush with the substrate surface. A small bulb planter will work in loose soils, but the planter style in Fig. 4C is much more efficient in heavier soils and when many traps are being deployed. The cup is partially filled with a preservative, typically ethylene glycol mixed with other liquids; however, propylene glycol is better because it is less toxic to curious wildlife that occasionally disturb traps. Traps should be covered with a lid as protection from rain and debris and weighted with a rock or brick to prevent smaller mammals from lifting the lid. Pitfall traps are best used for repeated field bioassays on a monthly, bimonthly or seasonal basis to measure phenologies of the target taxa. Pitfall traps provide a relative measure of arthropod

Fig. 4 Collection methods. (A and B) Tullgren funnels. (C–E) Pitfall traps. (F) Shaker box. (G) An aspirator.

field density that fall into the traps, but cannot measure true density because we don't know the relative propensity for each taxon to fall into the trap, and we do not know the extent of the surrounding area from which individuals are drawn.

A shaker or sieve made of food containers and a piece of coarse screen is a good way to separate small arthropods from organic litter (Fig. 4D and E). A handful of surface debris is placed in the apparatus and shaken over a white pan, after which individuals can be gathered with an aspirator or dumped directly into preservative. The method can be made somewhat quantitative by shaking equal masses for a predetermined period of time before aspiration.

It must be noted that molecular analysis of specimens for identification, intestinal contents and chemical composition is becoming a near-essential approach in ecological and behavioral studies for objectives, such as identification, identification of food and microbiomes, and chemical composition. Tullgren funnel extraction, collection via shakers or individual collection by sight into 95–100% ethanol will provide much better specimens for molecular work than most pitfall trap collection liquids.

Arachnida

Spiders, mites, harvestmen, scorpions, pseudoscorpions and about a dozen other small taxa are included in the class Arachnida. They are united in the possession of a body with two tagmata (major sections): the prosoma, equivalent to the head + thorax (thus also termed the cephalothorax), and the opisthosoma (or abdomen). Even when the body appears to be a single unit, as in mites and harvestmen, the distinction is still usually obvious, at least on the ventral side. Arachnids have eight legs as adults and two pairs of distinctive mouthparts, the chelicerae and the pedipalps. These organisms have a limited number of juvenile stages and do not molt after reaching adulthood.

Acari (mites)

The most biodiverse taxon of non-insect soil and litter-dwelling arthropods. Their higher classification has been altered in recent years due to new molecular-based studies, but no matter the arrangement, mites are extraordinarily diverse, with nearly 350 recognized families and over 48,000 described species. Nevertheless, many authors believe that may be just a fraction of the actual number. The discussion below is very general as mites are so morphologically, ecologically and behaviorally diverse. Ticks also are members of the Acari and occasionally fall into pitfall traps but are not considered further in this discussion.

In addition to being mega-diverse, mites occupy every conceivable terrestrial niche, with an astonishing variety of morphologies (Fig. 3B and Figs. 5–9) and life strategies. Mites have two tagmata: an anterior prosoma (or cephalothorax) that combines the feeding and sensory functions of the head with the more posterior part with the eight legs, and an opisthosoma, the body region posterior to the legs and bearing the genital orifice and the anus. Like other arachnids, mites have a pair of pedipalps and a pair of chelicerae for sensory and feeding functions. Some families of mites have a single pair of eyes, but otherwise mites are largely blind. Mites navigate their environment with sensory input from pores, setae and other organs on the body and appendages. Mites lay eggs, which hatch as six-legged larvae (Fig. 6A), followed generally by three instars before coming adult. Mites do not molt after reaching maturity.

Food

The anterior mouthparts function to grip, macerate and usually liquefy food items before ingestion. Pedipalps detect suitable food and may be modified to hold or tear prey. Reddish trombidiform mites (Fig. 5A–D) are common in spring and are easily seen, sometimes in large numbers, running over the ground or on logs and low plant material, seeking small arthropods for food. The pedipalps are modified for piercing and are much larger than the inconspicuous chelicerae. In most mites, however, the chelicerae are better developed as pincer-like claws (chela). The shapes of these chelicerae indicate the probable food of mites. Predacious mesostigmatid mites (Fig. 5E and F) have strongly toothed chelicerae for gripping and tearing prey, whereas detritus-feeding oribatid mites (Fig. 5G–J) have heavy pliers-like chelicerae for cutting tough bits of organic matter. Other predators include bdellid mites (Fig. 6B and C), with long, slender chelicerae that can reach deep inside prey and churn it up. The distinctive yellow astigmatid genus *Labidostoma* (Fig. 6D and E) has the movable digit on the claw interlocking with the fixed digit, reducing the chance for prey to get away. These variations are just a fraction of the variability in chelicera shape and function. Body form in soil mites tends to be correlated with herbivory or predation. Predators have long legs, long pedipalps and have slightly to moderately thickened or leathery cuticles. These mites can flee when confronted with a larger enemy. Slower-moving detrital feeders, exemplified by the enormous suborder Oribatida, usually have an armored body, resistant (although not impervious) to penetration by claws and teeth. Some oribatids (“trash mites”) have modified setae that allow accumulation of shed exoskeletons and other debris on their backs to discourage or fool predacious mites, spiders and insects (Fig. 21A).

Habitats

Mites are abundant nearly everywhere other life exists. Most ground-dwelling mites live in the leaf litter zone but the more active predators may roam freely up and down plant stems searching for their next meal. In this behavior they overlap with the many plant-feeding mites.

Interactions

Given their abundance, mites constitute a significant food resource for other soil invertebrates. Several families of small beetles are specialists on armored oribatid mites, including the innocuous-looking Ptiliidae (Fig. 2A), which use a variety of specialized methods to breach the cuticles of these mites.

Phoresy or not

“We gotta get out of this place, if it’s the last thing we ever do...” — The Animals (1965).

Phoresy is the behavior by which invertebrates, usually with limited dispersal capabilities, are transported by another organism to new habitats and resources. This mechanism is particularly common for organisms that exploit ephemeral food resources in patchy environments, for example, cattle droppings in a large pasture. These rich sources of food for nematodes, insects and mites are rapidly exploited and depleted, requiring transport, usually via beetles and flies, to a fresher source. Even in seemingly stable

Fig. 5 Mites I. (A–D) Trombididae (Order Trombidiformes). (A) Habitus of a red velvet mite. (B) Approximately 300 collected in a single pitfall trap. (C) Pedipalp. (D) Chelicera. (E and F) Order Mesostigmata. (E) Two of many forms. (F) Chelicera. (G–J) Oribatida. (G) Galumnidae, note lateral “wings”. (H) Phthiracaridae. (I) Nothridae. (J) Oribatid chelicera.

environments, a distance of a few centimeters may be too much for some small arthropods, and they may need to hitch rides on forest-floor insects or millipedes. Failure to reach a new favorable micro-environment can mean failure to reproduce.

Several groups of mites have evolved supremely effective means of catching rides on other arthropods, and some avail themselves of the opportunity to feed on their transport (Figs. 7–9). Phoresy is especially common on insects and millipedes. The third instar (deutonymph) is the usual passenger; it may be passively along for the ride or also actively feed on its transport. Bess beetles (Passalidae) are almost always infested with phoretic mites of more than one order. Three mesostigmatid species on the same beetle are imaged in Fig. 7A–D: a large species, a very small species (Fig. 7B and C), both favoring the thoracic venter, and a related species found only on the abdominal sternites (Fig. 7D, note differing setae on anterior end). Astigmatid deutonymphs

Fig. 6 Mites II. (A) Six-legged larva of Cunaxidae, body length 0.15 mm. (B and C) Bdellidae, entire specimen and chelicera. (D and E) *Labidostoma* sp. (Labidostomatidae), dorsal view and chelicera. Close-up of chelicera tip shows interlocking of digit and claw.

occur on millipedes (Fig. 7E–G), sometimes in large numbers. These mites have a specialized cluster of adhesive pads on the ventral side of the body, giving them a firm hold on the millipede. These phonetics can be gently removed and placed on agar streaked with bacteria. In a few days they will mature to adults and begin to lay eggs.

Another interesting approach to phoresy is that of uropodid deutonymphs that produce a stalk firmly cemented onto a beetle's body or appendages (Fig. 8A–C) (Bajerlein et al. 2016). The imaged scolytid beetle would seem to be aerodynamically disadvantaged, but it was caught in a flight intercept trap and must not have been significantly impaired.

Many apparent arthropod-mite phoretic relationships are really the larval mite stage feeding on a host and just incidentally getting moved somewhere else (Figs. 8D and 9). In Figs. 8A and 9E mite mouthparts appear to be firmly embedded in the host. These larvae may eventually detach and continue their development, but they lack the specializations of phoretic deutonymphs and therefore are not true phoretic mites.

Araneae (spiders)

Eight-legged predacious arthropods that make silk webs. Spiders have always been unjustifiably feared because of their venomous bites; but only a few of the 50,000 known world species are capable of doing any harm to humans whatsoever, and none actively chase humans to bite them. Rather, spiders occupy a key role in regulation of invertebrate communities by their feeding activity. All

spiders are predators on other animals, with the largest species capable of subduing and feeding on small mammals. Some species of semi-aquatic Pisauridae can catch small fish. All spiders produce silk from spinning glands in the abdomen for myriad uses but many active ground-dwelling species do not make prey-catching webs.

The order Araneae contains two infraorders. Mygalomorphae has chelicerae that parallel each other (paraxial), pointing posteriorly (Fig. 10A), while chelicerae of Araneomorphae point toward each other or cross (diaxial) (Fig. 10B). Mygalomorphs include the large tarantulas of movie horror as well as many smaller, even minute spiders. They are secretive, more common and more widespread than usually recognized. However, one tiny, 3-mm species, the spruce-fir moss spider (*Microhexura montivaga*) is a U.S. federally endangered species. Its habitat on the tallest mountains in Great Smoky Mountains National Park and other nearby mountains is disappearing due to the loss of the conifers that grace those peaks.

Araneomorphae contains the vast majority of spider species. Male spiders have enlarged pedipalps (Fig. 10F) with an intricate sclerotized apparatus for transferring sperm to a female. The intricacies are of vital importance in identifying araneomorphs to genus. Nearly all spiders have eight eyes, the arrangement of which is often useful in identifying them to family. The eyes provide depth perception for these predators to better insure a successful strike. Salticidae (jumping spiders) (Figs. 10D and 11C–E) have an enormous pair of medial eyes that detect slight movements of potential prey and allow the spider to calculate the length of jump needed to catch its prey. Foelix (2011) likened this behavior to that of a cat stalking a mouse. Wolf spiders (Lycosidae) also have large medial eyes for active hunting (Fig. 10E). In contrast, ambush hunters like crab spiders (Thomisidae) have smaller eyes (Fig. 10F); they tend to wait for prey to come to them. Grass or funnel-web spiders (Agelenidae) have smaller eyes (Fig. 10G) and construct webs for snaring prey, rather than actively hunting. The tiny spiders in Linyphiidae (Fig. 10C) also build webs but many species have their eyes on an enlarged, elevated cephalothorax.

Fig. 9 Doubtful mite phoresy: six-legged larval stages on small arthropods. (A–C) On flies; mites in (A) and (B) likely were feeding on the insect while traveling for free. (D) On Scelionidae (Hymenoptera). (E) Larval stage feeding on an oribatid mite. Transportation on these hosts likely is an accidental result of feeding. Although the fly in (C) seems badly unbalanced with the mite attached to its mouthparts, it was nevertheless able to be caught in a flight intercept trap. The scelionid was collected in a pitfall trap.

Food

All spiders are predators and dine almost exclusively on insects, although some augment their diet with nectar and other non-animal foods. Myriapods and other spiders can also be on the menu, but noxious insects such as stinkbugs and those that fight back, like bees and wasps, are generally avoided. Spiders are generalist predators that attack prey small enough for them to overcome, self-selecting their prey by the qualities of the insect-catching webs they build.

Habitats

Soil and litter-dwelling spiders are closely tied to their environments, so that the spider fauna of a forest will differ markedly from that of a nearby meadow. Colonization of new habitats is difficult if walking is the only way to get there and phoresy is very rare in the Araneae. Instead, young spiders of many families disperse by ballooning. When atmospheric conditions are favorable, spiders will climb to a high point, raise their abdomens and release a long silk strand that can catch a slight breeze and lift the spider into the air. Needless to say, undirected dispersal has a high mortality associated with it, but theoretically only a male and female need to

Fig. 10 Predators with eyes upon you: spiders and a beetle. (A–G), Araneae (spiders). (A) Parallel cheliceral fangs of Mygalomorphae. (B) Opposed cheliceral fangs of Araneomorphae. make the flight successfully, land in the same place and find each other to establish the species in a new place. Thousands of linyphiid spiders may launch at the same time, enhancing the chances for successful colonization.

Interactions

Spiders generally are solitary creatures but do not defend large areas around them, although exceptions occur. Spiders tend to avoid other spiders unless it is mating time. Predators of spiders include most famously the spider wasps (Pompilidae) and some members of the thread-waisted wasp family Sphecidae, especially mud daubers. Spiders also are prey for small insectivorous mammals and birds. Numerous parasitoid insects develop in spiders or their egg cases. Mermithid nematodes also develop inside spiders (Fig. 17C).

Several families of spiders, especially Salticidae, contain species highly modified to resemble ants (Formicidae), bethylid wasps (Bethyidae) or velvet ants (Mutillidae) (Fig. 11). Salticids are most advanced in this respect. The species shown in the figure were all

Fig. 11 Ant mimics: who's mimicking whom? (A) Ant (Formicidae). (B) Wingless bethylid wasp. (C) Jumping spider (Salticidae) slightly modified by constriction of abdomen. (D and E) Lateral view and left-side eyes (arrows) of highly modified salticid. (F and G) Lateral view and anterior cephalothorax of a similar spider (Corinnidae).

collected in the same general area in central Tennessee. Tropical salticids may be much more highly modified. A corinnid spider nearly identical to the salticids was collected in the same area but was easily distinguished by eye size and arrangement. It seems likely that these outwardly similar forms provide "group protection" and additionally avoid each other.

Opiliones

Long-legged arachnids known as harvestmen or daddy longlegs. These common arthropods are among the most unusual of all, with a little oval body suspended from eight impossibly long legs and the prosoma surmounted with a two-eyed observation knob, the ocularium (Fig. 12B and C). Harvestmen usually have cryptic patterns and colors that blend them in with their background

Fig. 12 Harvestmen. (A–D) Sclerosomatid harvestmen: habitus, eye tubercle of two species, chelicerae. (E and F) An armored harvestman, *Vonones sayi* (Cosmetidae): habitus (posed), paired eyes not on distinct tubercle. Fig. 5A courtesy of Adrian Smolis.

(Fig. 12A). Most people are used to seeing the very long-legged species but there is surprising variation in appearance, for instance the family Cosmetidae (Fig. 12E and F). Unlike the “typical” harvestmen, the ocularium is rudimentary and the eyes are distantly spaced. The following paragraphs are derived primarily from information in a splendid volume by Pinto-da-Rocha et al. (2007).

Harvestmen are typically included with the soil fauna, but many of the most common species are more likely to be on leaves or tree trunks. Pitfall traps, however, can collect many immatures and smaller species, especially in spring. Most harvestmen are generalist predators, using their pedipalps to hold the prey in place and the long, mobile chelicerae to tear it apart (Fig. 12D).

Fig. 13 The basal hexapods. (A) Protura. (B) Collembola, Isotomidae. (C) Collembola, Dicyrtomidae. (D) Diplura, Campodeidae. (E) Diplura, Japygidae. (F) Archaeognatha. (G) Zygentoma, Nicoletiidae. (E) by Mark Muegge, (F) by Matthew L. Bowser.

Harvestmen host an impressive array of parasites and parasitoids, as well as being potential food for members of every vertebrate class. They are, however, not defenseless. Harvestmen secrete noxious compounds from glands opening on the lateral margins near the coxae of the anterior legs. Consequently, harvestmen are distasteful and repellent to many would-be predators (although not all). The gland aperture is an ozopore, analogous to the defensive system of millipedes.

Pseudoscorpiones

Arthropods that resemble tiny scorpions that have lost their tails (Fig. 8E and F). They all are predators. Several species are anthropophilic but most of the nearly 3500 species are inhabitants of the soil, leaf litter, caves, bird nests and mammal burrows.

Pseudoscorpions have stout pincers-like chelicerae and prominent pedipalps with large pinching chelae reminiscent of scorpions. In most species the chelae have venom glands for subduing the prey. One or two small eyes are usually present on each side of the head. The life cycle consists of the egg, three juvenile stages and the adult, and is quite long for such little creatures, from 6 months to more than a year. Pseudoscorpions produce silk from glands on their chelicerae, which many species use it to spin a chamber for protection while they brood their eggs.

Pseudoscorpions are secretive and adept at hiding in small spaces. The pedipalps have long setae sensitive to the slightest air movement. If one moves an object close to a live pseudoscorpion it will energetically back up and raise its claws. They prey on small Collembola and other small arthropods. Phoresy is a common dispersal feature of pseudoscorpions. Unlike mite deutonymphs, it is the adult stage of pseudoscorpions that latch on to insects with their pedipalps (Fig. 8E and F). For them it is strictly a ride; they have never been reported feeding on their winged hosts, at least in flight.

Basal hexapods

Basal hexapods (Fig. 13) are three arthropod classes (Collembola, Diplura, Protura) and two insect orders (Archaeognatha, Zygentoma) whose ancestors never developed flight capabilities. These five taxa often are referred to as apterygotes. All are clearly recognized as separate but for convenience Archaeognatha and Zygentoma are sometimes discussed together. The term ‘apterygote’ refers to being wingless, which is true for the classes and orders indicated, but also can apply to any wingless insects such as fleas and lice, which are descended from winged forms. The five should be called basal hexapods; they all have six legs as in insects but lack the lateral pleural regions that are part of the later-evolving thoracic “box” for powered flight. Collembola, Diplura and Protura differ from true insects in having mouthparts enclosed by the head capsule, so that the mandibles and maxillae are hinged to internal tentoria. True insects have these parts hinged externally on the head capsule. Several molecular studies have confirmed this phylogenetic separation. Unlike the winged insects all basal hexapods practice external fertilization; males deposit sperm packets or droplets that nearby females pick up, sometimes after a mating dance.

Individuals of Collembola, Diplura, Archaeognatha and Zygentoma molt continuously throughout their lives, during which they can regenerate appendages lost to predation or accident. Protura, on the other hand, have five or six post-embryonic stages depending on subclass. Molting proturan adults have not been reported in the literature.

Collembola (springtails)

An exceedingly ancient class of hexapods dating at least to the lower Devonian. About 9000 species have been described worldwide, but as with most of the higher taxa mentioned in this chapter, that number probably is just a fraction of the true number. Many of the families are abundant and widespread (Fig. 14). The common name derives from an appendage on the venter of the fourth abdominal segment, the furcula, formed by the fusion of the former legs of that segment. However, many soil springtails have a reduced furcula or lack one entirely. Genial habitats may have 15–60 species that can reasonably be considered sympatric. Collembola living in the litter layers often exhibit vivid colors and patterns or are covered with scales that form light-reflective patterns.

Springtails lay eggs. Developing juveniles grow by molting through several stages but also continue to molt as adults. *Folsomia candida* (Isotomidae), the standard laboratory research springtail, may have up to 40 molts, with egg-laying commencing after the sixth molt. Females alternate egg-laying and non-egg-laying stages. Many species of Collembola are parthenogenetic, apparently facilitated by endosymbiotic *Wolbachia* bacteria.

Food

Springtails often are often thought to be mostly fungal feeders, but the evidence speaks to a far more varied diet for many species (Chahartaghi et al. 2005). Larger species skeletonize leaves and eat lichens that have fallen to the ground (Fig. 15A and B). Many species will readily consume a wide range of plant, fungal and animal tissues presented to them in the laboratory, although that is not always an accurate assessment in natural conditions; litter quality is important in determining the rate at which Collembola and other detritivores process organic matter (Ma et al. 2019). Collembola have two separate approaches to ingestion. Most families have chewing mouthparts, while a few families (e.g., Neanuridae, Odontellidae) have modified mouthparts that suggest a piercing-sucking mode of feeding. However, within sympatric species of a single genus these modified mouthparts may differ enough to suggest resource partitioning. For example, three sympatric species of *Morulina* have markedly different mouthparts (Fig. 16A–C) and the intestinal contents of each differs from the others (Bernard 2006). *Morulina crassa* (body length 1.4–2.2 mm) contained large pieces of hyphae, whereas *Morulina callowayia* (3.0–3.4 mm) ingested much finer hyphae, and the intestine of *M. delicata* (2.4–3.8 mm) was devoid of solid material. Likewise, species with chewing mouthparts co-exist in the same microhabitats by having food preferences. For instance, three ground-dwelling species in a fescue field had distinctly different arrays of food in their intestines (Fig. 16D–H). Members of the genus *Metisotoma* (Isotomidae) have mandibles and maxillae highly modified for prey capture and nestled in an atypically large head with enhanced muscles. These springtails wait in ambush for small prey (especially other springtails) to walk by; they then rush forth to bite their prey and consume it. Predation or carnivory can frequently be observed in culture. *Pogonognathellus* (Tomoceridae) are almost instantly attracted to an injured springtail and will eat it (Fig. 16F).

Fig. 14 Collembola diversity. (A) *Lobella palmeri* (Neanuridae). (B) *Vitronura* sp. (Neanuridae). (C) *Paronychiurus ramosus* (Onychiuridae). (D) *Orchesella cincta* (Orchesellidae). (E) *Entomobrya zona* (Entomobryidae). (F) *Orchesella carneiceps* (Orchesellidae); note that Collembola stand on the tips of their claws. (G) Head of *Pogonognathellus* sp. (Tomoceridae), note 6 eyes and body scales. (H) *Lepidocyrtus beaucatcheri* (Entomobryidae). (I) *Pseudosinella* sp. (Entomobryidae). (J) *Megalothorax maculosus* (Neelidae). (K) *Ptenothrix marmorata* (Dicyrtomidae). (L) *Sminthurinus quadrimaculatus* (Katiannidae). (M) *Pararrhopalites* sp. (Arrhopalitidae). (N) *Allacma fusca* (Sminthuridae).

Note holes chewed in leaf and scattered blackish fecal pellets. (B) A dead leaf thoroughly skeletonized by detritivores, likely including small millipedes, isopods and Collembola. (C and D) Video captures of *Protaphorura fimata* (Onychiuridae) tunneling in roots of rooted maple cuttings. This species is one of the very few economically important pest springtails on living plants. (C) Antennae protruding from hole in excavated root. (D) Moving through tunneled root.

Habitats

Springtails are the most abundant and widespread of all hexapods, occurring wherever some suitable food is available. Several species are endemic to the Antarctic mainland, and a diverse fauna exists above the Arctic Circle to the northern rims of the continents. Habitat variety is endless; every vegetation site will produce a range of species adapted to it. Several families are partly or wholly arboreal, often being collected as stray specimens that have fallen to the ground. Other species in the Tomoceridae and Sminthuridae are not truly arboreal but climb tree trunks to feed and hide, and many species of Entomobryidae and Katiannidae climb herbaceous plants early in humid mornings to feed on pollen and fungal spores. *Hydroisotoma schaefferi*, associated with streams, hides between moss scales to escape predation by rove beetles (members of the family Staphylinidae). A few species are plant pests; *Sminthurus viridis* is an economic pest of alfalfa, scraping the epidermis of leaves and dehydrating them, while *Protaphorura fimata* tunnels through roots of tree seedlings, resulting in their decline and death (Fig. 15C and D).

Interactions

According to USDA entomologist Ian Stocks, Collembola can be thought of as “cows of the forest floor” since by their great abundance they are a major food source for the many small predators that roam the same environments, especially mites, spiders, ants and beetles. Ants (Formicidae) and crab spiders (Thomisidae) can often be seen scuttling around with springtails clutched in their chelicerae and may hang onto them even after falling into pitfall traps (Fig. 17D and E). *Stenus* species (Staphylinidae) (Fig. 10H and I) are specialist springtail predators. These beetles have enormous eyes for their size, allowing them excellent vision for spotting springtails and an extensible sticky labium for catching their prey, which is immediately hauled back to the mandibles and maxillae for consumption. Springtails can be colonized by *Entomophthora*-like fungi (Fig. 17A) and occasionally are infected with mermithid nematodes (Fig. 17B), although these are probably accidental infections of aquatic nematodes coming into contact with the springtails due to stream flooding.

Diplura

A class of basal hexapods consisting of about 700 species worldwide (Fig. 13D and E). Two of the three superfamilies (Campodeoidea, Japygoidea) are found worldwide in soil, litter and under rocks or moss mats on rocks in moist environments. These arthropods all lack eyes and are at least partially carnivorous on small, soft-bodied soil fauna, but campodeids also are detritivores and fungivores. Diplurans lay their eggs suspended on one or more stalks in a soil cavity or space. Females guard the eggs

and clean them of contaminants and potential pathogens until they hatch. Diplurans molt throughout life and so vulnerable appendages are regenerated over time.

Campodeoidea have long, slender cerci (Fig. 13E). They are very fast runners, moving quickly to find shelter when exposed. As they run, they wag their cerci, presumably as a distraction for potential predators. Japygoidea are instantly recognizable by the presence of pincer-like cerci (Fig. 13D), thus bearing a fleeting resemblance to young earwigs. The body is weakly sclerotized except for the final segment and the cerci. Members of Japygidae feed by capturing prey with their mandibles, then reaching over the body with the cerci to hold it while mandibles and maxillae chew it up. One family of very small Japygoidea, Parajapygidae, is a true soil dweller and feeds on plant tissue.

(Tomoceridae) infected with mermithid nematode. (C) Mermithid nematode exiting its spider host. (D and E) Entomobryid Collembola captured by an ant and a crab spider, respectively. (F) *Pogonognathellus* individuals attracted to and devouring an injured springtail (*Lepidocyrtus paradoxus*, arrow).

Protura

A class of six-legged arthropods separate and distinct from insects (Fig. 13A). The first proturans were discovered in 1907; since then, more than 800 species have been described from every continent except Antarctica. This number undoubtedly is far short of the actual number of species, as regional surveys typically find numbers of undescribed species. Adult proturans are less than 2 mm long and amber-colored. Protura lack eyes and antennae are absent, but the front legs are enlarged and held forward to take their place, with the middle and hind legs doing most of the walking. The mouthparts, which are held within the head capsule, except when feeding, are slender and more-or-less pointed.

All proturans have five postembryonic stages: prelarva (nonfeeding), larva I, larva II, matus junior, adult. Additionally, in Eosentomidae, developing males have a separate pre-imago stage before molting to functional males. The stages are easily separated from one another, thus large collections can be used to develop phenologies.

Tullgren funnels are best for collection of most Protura. For the small species that dwell in mineral soils high-gradient extractors are useful and sucrose flotation methods used for nematodes can lift them free from mineral components, though often with the loss of one or both forelegs. Protura rarely fall into pitfall traps and direct examination of the habitat for these secretive arthropods usually is an exercise in frustration.

Food

Proturans feed on fungi and may favor ectomycorrhizal fungi, but so little observation has been done that proturan food limits are not yet well defined.

Habitats

Protura are most often collected from upper soil layers, especially the O-layers (Table 2) of forest leaf litter and can be quite abundant, with nearly 40,000 individuals per surface square meter (Krauß & Funke 1995), and they are often abundant in secondary oak forest, suggesting a close correlation to actively developing ectomycorrhizal fungi. Proturans are also found in grassy areas, but as grasses are not symbiotic with ectomycorrhizal fungi, proturans must have a broader range of fungal food sources such as individual hyphae or mycelial mats.

Interactions

Proturans are likely to be food for small beetles, spiders, pseudoscorpions and predacious mites, but their importance as prey has not been documented. Proturans seem to have at least two active defense mechanisms. When disturbed from behind, a proturan may suddenly extend its abdomen to poke the offender. Proturans also exude a sticky substance from glands on the eighth abdominal tergite that may enmesh the mouthparts of predators (Hansen et al. 2010).

Interesting fact

Protura hatch with 9 abdominal segments and add new ones as they develop and molt, to a total of 12 (anamorphosis). However, they don't add one at each molt. The five instars have 9 (prelarva), 9, 10, 12, 12 (adult); there is no 11-segmented stage. In the subclass Eosentomata there is a "preimago" male, in which all characters are those of a mature male except the genital apparatus is not fully developed. If the female stage has a similar molt it is identical to the mature female.

Archaeognatha

The jumping bristletails were once included with the silverfish in the now obsolete order Thysanura. The order is also called Microcoryphia. Archaeognatha comprise about 500 species distributed worldwide. This insect order is exceedingly ancient; their fossils represent some of the first insects to appear on earth, and still bear many archaic traits. The extinct order Monura is now recognized as early Archaeognatha. The members of this order are the only monocondylic insects, referring to the mandibles being hinged to the head capsule by only one distinct condyle. All extant archaeognaths are robust insects with a cylindrical, tapering, arched body that can be forcibly snapped, propelling the insect upward some distance when it is disturbed. The ventral abdominal plates each bear a pair of coxites, remnants of the abdominal legs seen in the earliest fossils. All species have a body covered in frequently iridescent scales often forming a cryptic pattern, enormous compound eyes, large ocelli below the compound eyes, a pair of long cerci and an even longer terminal filament. This terminal filament plays an important role in stabilizing an airborne individual; damage to the filament adversely affects the jump (Yanoviak et al. 2009). Sturm & Machida (2001) describe collection and rearing of these ancient insects, as well as presenting keys to the world genera.

Food and habitat

Most archaeognaths tend to occur on rocks, piles of stone or rock crevices where their scale pattern blends with the rock surface (Fig. 13F), but in forest they can sometimes be found on tree trunks. Food consists of algae, lichens, detritus scraped from leaves or wood surfaces and sometimes leaf surfaces themselves. Investigation of the ability of these insects to use a wide range of plant foods would help complete gaps in knowledge of this resilient insect order.

Interactions

Gregarine protists (see Diplopoda section) are present in the midgut of many archaeognaths but their effects, if any, are unknown. Mermithid nematodes have been reported but could well be accidental infections. The few reports of predators are mostly for spiders and the occasional rove beetle. Interactions of these relatively large charismatic insects with parasites and predators could be studied to good effect without expensive equipment.

Zygentoma

The silverfish and related taxa consist of about 600 species. The best-known, of course, are the anthropophilic silverfish in the family Lepismatidae, but five other families exist including Nicoletiidae and Tricholepidiidae. This latter is known from one species in a small area of California. Zygentoma are rather flattened, quick-moving insects with three “tails” (two cerci, terminal filament) of about the same length. Lepismatidae are scaled and have a small cluster of ocelli on each side of the head, while in Nicoletiidae eyes are lacking and scales are present or absent. Zygentoma mouthparts are dicondylic, with two hinge points for each mandible.

The lepismatidae genera *Lepisma*, *Ctenolepisma* and *Thermobia* contain most of the species considered to be domestic pests (Wygodzinsky 1972), but they thrive outside if the climate is suitable, especially *Ctenolepisma*. They can easily slip back inside due to their flattened bodies and nocturnal movements. The damage they cause by eating starchy material, book sizing, etc., can be significant but is not often seen today, perhaps due to a widespread adoption of air conditioning. Rust & Millard (2009) provide management guidelines. My home has a light infestation of the four-lined silverfish, *Ctenolepisma lineatum*, and several buildings on the University of Tennessee campus have the gray silverfish, *C. longicaudatum*, but I like the philosophy expressed by the entomologist F.E. Lutz (1948, p. 40): “If such a creature is eating your wallpaper...or other belongings, your sorrow may be mitigated by your interest in seeing the most primitive insect you are likely to observe without special effort.”

Although much is known about these domestic companions, much less attention has been paid to the other members of the family. Pitfall traps in temperate areas remote from human habitation sometimes contain lepismatidae, but identification is usually not possible because those biotopes have never been surveyed. When collections are made in a region and modern molecular techniques are deployed as well as morphological description for species analysis, numerous new taxa may be identified (see Smith 2017).

Nicoletiidae is a widespread subtropical-tropical family with a few representatives reaching to the mid-temperate latitudes. These secretive members of Zygentoma do not inhabit homes although one or two species are widespread in greenhouses. Nicoletiidae has two subfamilies: Nicoletiinae are slender, have long tail filaments and tend to live in soil, litter and caves, while Atelurinae (Fig. 13G) are wedge-shaped with short tail filaments and are often associated with ants. Both subfamilies contain many undiscovered species.

Food, habitats, interactions

Zygentoma are generalist feeders, eating a wide range of materials. The diets of Nicoletiinae have not been elucidated, but corn root traps in caves have successfully attracted them. Atelurinae are largely associated with ants but not in a tight symbiotic relationship or commensal relationship. Tolerance of the ant host for the presence of inquilines and social parasites is dependent on the ability of the “guest” to exhibit behavioral and chemical mimics that mark it as a fellow ant (von Beeren et al. 2021). Atelurines were more subject to attack by their hosts than were some other guests due to their quick movements that signaled a colony intruder.

Crustacea

Crustacea are overwhelmingly aquatic organisms, with enormous diversity in both marine and freshwater habitats. However, several classes and orders have managed to find a semblance of life ashore. Most of these groups are dependent upon a very moist environment and periodic retreat to water, among them amphipods, crabs and crayfish. Others such as fairy and tadpole shrimps (Anostraca) complete their life cycles in ephemeral pools, then lay eggs resistant to desiccation until the return of free water. Small copepods are occasionally found in soil extracts. Ostracods occasionally show up in pitfall traps, an indication that they have been disturbed by flooding from a nearby stream; ostracods are strictly aquatic. The only fully terrestrial crustaceans are Isopoda of the superfamily Oniscoidea (woodlice, pill bugs, sow bugs, roly-polies) (Fig. 19A). Oniscoidean isopods, of which there are about 5000 species, have a cosmopolitan distribution.

Most crustaceans respire through gills, but terrestrial isopods have a highly modified lung-like system under the abdominal pleopods (pleopodal lungs, Unwin 1931; <https://www.bmig.org.uk/image/woodlice-pleopodal-lungs>); this modification allows them to live in a wide range of climates, although sufficient moisture is a necessity. Oniscoidea carry their eggs in a brood pouch between the leg bases. Hatched juveniles leave the brood pouch soon after hatch. Juveniles resemble the adults and go through four or five molts to reach maturity.

Food

Woodlice are omnivores, although some species may have decided preferences for certain kinds of plant litter. In laboratory culture they readily eat fresh vegetables and thrive alongside the millipedes therein. Woodlice also are coprophages.

Habitats and interactions

Terrestrial isopods are active and abundant in most mesic biotopes in leaf litter, loose soil, under rocks or beneath loose bark or pieces of wood. Regardless of habitat, terrestrial isopods are dependent upon high humidity and some free water to maintain internal water balance and operate their pleopodal lungs (Warburg 1987). Woodlice are vulnerable to beetles, spiders and other predators capable of penetrating their strong cuticle.

Myriapoda

“*Pauropus huxleyi* is a bustling, active, neat, and cleanly little creature. It has, too, a look of cheerful intelligence, which forms a great contrast to the dull stupidity of the Diplopods, or the melancholy ferocity of most Chilopods.” — Sir John Lubbock (1868).

"One who once has seen a living pauropod, like a miniature mouse scurrying around on the dark underside of a stone with quick elegance, will certainly concur with him." — Ulf Scheller (2011).

(Referring to the house centipede, which eats insects and spiders): "Dr. Felt says 'its presence in a house should be welcomed, since it is capable of inflicting no injury aside from a somewhat poisonous bite, the latter being extremely rare.' I confess that any found in our house get stepped on." — Frank E. Lutz (1948).

Myriapoda is a clade of four arthropod classes (Chilopoda, Diplopoda, Pauropoda, Symphyla), with the distinction of containing the world's largest known land arthropod, an extinct millipede relative that may have been more than 2.5 m long with a mass of 50 kg (Davies et al. 2021). The extant members are all much smaller, with the African millipede *Archispirostreptus gigas* reaching 30 cm long and weighing 100 g (Fig. 20A), and several scolopendrid centipedes nearly as long. In contrast, most pauropods are less than 2 mm long. Myriapods are mandibulate arthropods with two main body divisions (head, trunk), one pair of antennae and many legs. They are all terrestrial and most occur in soil and litter.

Chilopoda (centipedes)

Myriapod class of predators with one pair of legs per segment. Anthropomorphism is an outdated approach to understanding the nature of invertebrates, but most people recoil upon the sight of a centipede...fast-moving, fangs, too many legs and overwrought stories of their venomous bite. The 3000 species of centipedes are easily recognized by their slender, amber-colored bodies and rather fearsome "fangs" (forcipules) that are really the highly modified first pair of legs modified for injecting toxin into prey (Fig. 18E and F).

Adults of the four common centipede orders are readily identified. Scutigermorpha (of which the house centipede is best known) have 15 pairs of legs and large compound eyes. The other orders have small eyes or are blind. Lithobiomorpha have 15 body segments bearing a pair of legs; Geophilomorpha are slender and have 31 to more than 180 segments with legs; and Scolopendromorpha have 21 or 23 leg-bearing segments. A fifth order, Craterostigmomorpha, occurs in Tasmania and New Zealand. Interestingly, the venom composition among the centipede orders varies substantially among the orders (Jenner et al. 2019).

Females of geophilomorphs and scolopendromorphs brood their eggs and hatchlings, which have the same complement of legs as the adults. Lithobiomorphs and scutigermorphs lay eggs singly, and hatchlings have only a few pairs of legs. The number of

Fig. 20 (A) The African Giant Millipede, *Archispirostreptus gigas*; largest individual 28 cm (Order Spirostreptida). (B) Gregarine protists (Apicomplexa) attached to inner wall of everted intestine of the American Giant Millipede, *Narceus americanus*.

post-embryonic molts is variable among the orders, generally 7–11 (Lewis 1981). Chilopoda are typically long-lived with only one generation per year. Centipede densities are smaller than those of their prey, with an upper limit of about 1000/m² for geophilomorphs, but other orders typically have much smaller densities. However, the bulk of this work has been done in northwestern Europe, with few tabulations from other regions.

Food

All centipedes are predators inhabiting soil or litter. Specific enzymes are produced in centipede venom to digest prey tissues. Choice of prey is not very selective; various observations have shown that any invertebrate encountered could be a target. In laboratory studies, some potential prey items may be rejected, but whether rejection is uniform among an isolate, population or species is an open question. The larger scolopendrids can be predators of small vertebrates, including bats. Herbivory has been reported but is probably due to incidental organic matter ingested along with prey or consumed in stressful conditions.

Habitats

Scutigermorph centipedes are long-legged, swift surface runners native to tropical and subtropical regions. The house centipede, *Scutigera coleoptrata*, is a nearly cosmopolitan inhabitant of houses, but can also occur on the soil surface, in crevices and among log piles in the vicinity of human habitation. Other species may opportunistically inhabit rodent burrows (Voigtländer, 1981). Most scolopendromorph and lithobiomorph centipedes inhabit leaf litter, soil cracks and spaces and under the bark of cut and fallen trees and logs. A good place to locate them is on soil under rocks, especially flat ones with worm and insect tunnels that provide space for them to dwell. Some centipedes are capable of burrowing, especially as a defense against desiccation. Most centipedes are nocturnal organisms, although scutigermorphs may also be active in lighter conditions.

Interactions

Snakes, lizards, birds and small to medium sized mammals, from shrews to foxes, have all been reported to prey on centipedes, although there are few or no records of predation on scutigermorphs. Carabid beetles may be significant predators of smaller individuals. Centipede digestive tracts contain a diverse array of gregarine, coccidian and other protists that probably are harmless commensals. Nematode infection is very rare; oxyuridomorph nematodes, which are common in millipedes and soil insects, are unknown in Chilopoda except perhaps for one report of a *Cephalobellus* sp. However, centipedes apparently can serve as an intermediate host for the human parasite *Angiostrongylus cantonensis* (rat lungworm), a causal agent of eosinophilic meningitis (<https://www.cdc.gov/parasites/angiostrongylus/index.html>). Wang et al. (2018) described cases in China of persons who acquired this parasite from eating raw centipedes.

Diplopoda

The millipedes, a myriapod class of more than 7000 described species (Figs. 19B–H and 20A). Millipedes are instantly recognizable by the two pairs of legs on each body segment, formed in the distant past by fusion of two body segments each with a single pair of legs. This fused segment is better termed a diplosegment or body ring. Fusion must have occurred nearly a half-billion years ago, as all known millipede-like fossils have this feature. In living species, this fusion strengthens body architecture and allows a stronger push when millipedes are burrowing through soil or leaf litter. The body architecture further allows most millipedes to roll up in a tight spiral protecting the more vulnerable underside. In cross-section millipedes are largely cylindrical, hemispherical or flat, but Glomeridae and Sphaeriodesmidae resemble large isopods and similarly can roll up into tight spheres. Millipedes typically are solitary animals but platydesmids (Fig. 19E) usually are found in small groups on covered damp wood or bark.

Another signal feature of millipedes is the presence in most species of a chemical defense system, consisting of a pair of glands in each segment with an outlet (ozopore) through the body wall. Hydrogen cyanide (HCN) is common in the order Polydesmida but many different combinations of noxious chemicals exist among most of the other orders. The common polydesmid family Xystodesmidae (Fig. 19D) seems particularly pungent. Paradoxically, flies adapted to feeding or laying eggs on dead arthropods (Phoridae, Sarcophagidae) are drawn within a minute to a crushed millipede, presumably due to the release of the pungent defense chemicals. In our laboratory experience, millipedes in culture for months or gently handled repeatedly become acclimated to these situations and cease to release defensive chemicals.

Millipedes range in size from tiny soft-bodied polyxenids (Fig. 19F) to *Archispirostreptus gigas* (Fig. 20A), an African species that can grow to a length of more than 30 cm. The record for most legs is 1306 for the recently described Australian female of *Eumillipes persephone* (Marek et al. 2021), collected from a 60-m-deep exploratory drill hole. As discussed by Marek et al. (2021) and others, subterranean systems have numerous, cracks, fissures, faults and chambers where an almost unknown fauna may be hiding. Sinkholes likely include an underground chamber or cave that usually gets filled in with earth or concrete, destroying any ecosystem that exists in it.

Millipede development is anamorphic, with new segments added at each molt, at least until the adult stage is reached. The first-stage juvenile usually has five body segments and three pairs of legs; at first glance one might think they are springtails or strange beetle larvae. Some taxa continue to molt and add segments even after reaching adulthood, while others reach their segmental limit but need to molt a few more times to become sexually mature. Millipedes possess anteroventral gonopores, usually on the seventh body ring. At maturity males have a pair of highly modified, sometimes fantastically shaped legs, the gonopods, on the ventral side of the seventh body ring. These gonopods manipulate a sperm globule for insertion into the female's gonopore.

Mating is preceded by the male accompanying the female as she walks around or even riding on top of her. Eventually the two entwine venter to venter and the fertilization process occurs (Fig. 20D).

Food

Millipedes are major components of the detrital food web, consuming dead leaves, wood, fecal material from herbivores and their own droppings. Bacterial fermentation within the intestine is an important source of supplemental nutrition. Some species will eat live basidiomycete fungi (Fig. 20G). Fungal interactions with millipedes may be extraordinarily complex. In one extensive study *Brachycybe lecontii* (Fig. 20 is *Brachycybe petasata*) was associated with 176 fungal genera in 39 orders (Macias et al. 2019). The large species *Narceus americanus* (Fig. 20B) is often found on tree trunks two or more meters from the surface eating organic matter on bark. In our laboratory cultures spirobolida and spirostreptida are ready consumers of many fresh vegetables and denser fruits such as apple, with particular attraction to sweet corn and bell pepper (Fig. 19B, C, H and 20A), but in nature are found mostly in forest ecosystems, not in gardens. Millipedes can also be opportunistic carrion feeders on other invertebrates and even on dead millipedes. The reduction of large pieces of dead plant material to smaller pieces was long thought to enhance fungal and bacterial colonization, but Rawlins et al. (2007) demonstrated that digestion removes biochemical components useful to soil microorganisms, leaving behind biologically recalcitrant materials. However, weathering of fecal pellets probably disperses individual fragments so that even recalcitrant materials such as lignin are more exposed to their microbial specialists. Damage to living plants is rare but the introduced species, *Ommatoiulus moreleti*, has damaged crops in Australia (Douglas et al. 2019).

Habitats

Diplopods are most abundant in moist deciduous forests, where several species can be found moving about openly during the day, but more often at night. Millipedes also occur in meadow and grassland but are not as well known; hand-collecting and use of pitfall traps in these habitats will yield species that do not live in forest. Millipedes associated with the forest floor often move under bark on standing dead trees.

Interactions

The chemical defenses of millipedes repel many potential predators, but others are undeterred. David (2015) has summarized these successful predators, both mammalian and arthropodan. The large European staphylinid beetle *Ocyopus olens* (up to 32 mm length) is a generalist predator that feeds readily on *Ommatoiulus moreleti*, a medium-length millipede (up to 45 mm). The lack of suitable predators in Australia likely facilitated the dispersal and abundance of *O. moreleti*.

Internal parasites and commensals of millipedes exist in several kingdoms and phyla, including Protista (ciliates, gregarines), “trichomycete” Zygomycota fungi, Acanthocephala, Nematomorpha, Nematoda, and Arthropoda. Detailed discussion of the numbers and complexities of these groups is beyond the scope of this Chapter. However, as most of these taxa occur in the gut of the millipede, one should think of a “universe” within a millipede intestine. Most millipedes more than 2 mm wide are likely to contain nematodes, trichomycetes and ciliate protists in the long hindgut. Gregarines, a group of apicomplexan protists, will be easily noticed in the trophozoite stage protruding from the inner lining of the intestine (Fig. 20B). Nematodes are the most prominent members of millipede intestinal fauna. Hundreds of species in the nematode orders Rhigonematomorpha and Oxyuridomorpha have been described. Both of these orders are considered bacterivores and do not feed on millipede tissues. Adults of most of these nematodes exceed lengths of 2 mm and several can reach 10 mm. Although a large millipede may harbor hundreds of nematodes it remains active and appears healthy, suggesting no harm. The ease of millipede dissection and identification of intestine-inhabiting nematodes provides an excellent means for students to explore natural relationships of hosts and commensals directly from the field (Phillips et al. 2019). An unrelated bacteria-feeding nematode, *Rhabditis necromena*, is useful in millipede biocontrol due to carrying a pathogenic bacterium in its intestine that is released into the millipede lumen after the nematode has entered the host (Schulte 1989). It must be noted that many other species of Rhabditidae may invade millipedes when they are sick or recently dead, colonizing the hemocoel, collapsing tissues and reproducing rapidly. One must distinguish these opportunistic scavengers from nematodes transporting pathogenic bacteria.

Paupropoda

Tiny, inconspicuous arthropods with a head, 12 trunk segments and 8–11 pairs of legs (Fig. 18A–C). Development is anamorphic, with five active stages following egg hatch; total time from egg to adult is thought to be 3–4 months. The antennae are unique among the myriapods; they have two distinct branches (biramous), one of which has a basket-like sensory process, the globulus. Most species are whitish-translucent, but the family Eurypaupodidae (Fig. 18B) has enlarged, sclerotized tergites. Pauropods move in short runs, stopping frequently then continuing. Their distinctive darting movements make them easy to spot, even though most species are only about 1 mm long. About 830 species have been described but many await discovery; every in-depth survey reveals numerous undescribed taxa.

Starling (1944) studied the Pauropoda of Duke Forest (North Carolina) in field observations and laboratory cultures of *Paupopus carolinensis*. In both pine and oak forest soils pauropod densities were largest at soil depths of 2.5–5.0 cm, soil temperatures of 18 °C or above, soil moisture averaging 20% and high relative humidity. Pauropod densities may reach several thousand per m² in favorable environments.

Food

Pauropods are generalist herbivores or fungivores (Potapov et al. 2022). One species has been reported damaging root hairs of greenhouse-rooted African Violet (Scheller et al. 2004).

Habitats

Pauropods are creatures of moist soil, small enough to live in soil spaces. They also seem to favor the underside of rocks; they can be found by overturning a stone and looking for tiny white creatures darting about on the surface, from which they can be collected with a moistened paintbrush.

Interactions

There seems to be little or nothing known of predation on pauropods. Two families, including Eurypauropodidae (Fig. 18B), are “armored”, with thickened, more sclerotized terga, suggesting defense against predators. The tiny size of pauropods allows them to move through connected soil pores or between aggregates to avoid larger, less mobile predators.

Symphyla

Slender white myriapods with 11 or 12 pairs of legs, a pair of filiform antennae and lacking eyes (Fig. 20D). About 200 species of symphylans have been described. Most species are less than 5 mm long, but several may reach 15 mm. The posterior end of the body has a pair of cerci, each of which has a spinneret that produces silk. Symphylan development is anamorphic, with newly hatched juveniles having six pairs of legs and short antennae with only a few segments. They reach adulthood after five juvenile stages but continue to molt after maturity. In culture, adults may molt more than 50 times. Symphylans are surprisingly long-lived, up to 7 years in one study; this life span is comparable to that of the largest millipedes.

Although a common name for this class is “garden centipede” they are harmless to people. Note, however, that the centipede, *Lithobius forficatus*, also has the common name of garden centipede (e.g., see <https://homeguides.sfgate.com/garden-centipedes-76177.html>), but this arthropod is much longer and brown. Possible confusion of the two organisms is a good reason to just call Symphyla symphylans. Symphylan mouthparts resemble those of millipedes and even the largest species cannot bite. Symphylans are classified into two easily separated families. In Scolopendrellidae the posterior margins of the tergites have pointed posterior projections, whereas the Scutigereidae have rounded posterior margins.

Food

Symphylans are considered omnivores, capable of feeding on the softer parts of plants and animals. *Scutigereella immaculata*, a worldwide pest of live plants, was studied thoroughly by Michelbacher (1938), who fed his cultures with lettuce. Seedlings suffer the most damage due to root feedings and germinating plants may die before emergence above the soil surface. Plants that are several weeks old generally suffer little damage because the root systems are more robust, and roots and root cell walls are thicker.

Habitats

Symphylans live in leaf litter and soil. They can be found in most biotopes. Their slender, very flexible bodies move easily through soil channels formed by roots or soil structure and aggregation, enabling them to migrate deeply into soil.

Interactions

Because symphylans typically reside in soil, they are unlikely to encounter the usual suspects (spiders, harvestmen, small beetles, centipedes) unless they come to the surface to feed. Soil-dwelling beetle larvae (Carabidae, Staphylinidae, etc.) may be more likely enemies. Symphylans produce silk from glands on the cerci. Other arthropods that make silk tend to have multiple uses for it; for symphylans, these include anchorage during the molting process or as a defense against predators. Quite possibly, silk smeared on the mouthparts of a predator will deter the attacker.

Camouflage, mimicry and defense

Staying alive and well long enough to reproduce is a constant challenge for all organisms. Arthropods have evolved a wide array of adaptations to lessen the chances of being eaten, including camouflage, mimicry, chemical defenses and impersonation. Only a few examples can be given here but readers are invited to find others.

Some arthropods disguise themselves as debris, which not only blurs the arthropod’s dimensions but also reduces the chance of a successful attack through the debris. The “trash” oribatid (Fig. 21A) has already been mentioned. Larvae of Chrysopidae (green lacewings) are similarly modified with cuticular lobes and long setae to hold debris on their backs as a disguise. Camouflage also can be an intrinsic part of the arthropod’s body. Some springtails (Fig. 21B) have scale patterns that break up their outlines and resemble the substrate on which they are resting. Species of Dicyrtomidae (Fig. 14K) mimic linyphiid spiders and even have a similar walk.

Chemical defense is an important deterrent mechanism for several families of poduromorph Collembola, especially Hypogasturidae, Neanuridae, Onychiuridae and Tullbergiidae. When a threat is perceived or they are physically attacked, these springtails

Fig. 21 Camouflage, mimicry, defense and “I’m with you”. (A) Oribatid “trash” mites with old exuviae and debris clinging to long body setae and feathery leg setae. (B) *Pseudachorutes aureofasciatus* (Neanuridae) (left), putative neanurid mimics *Anurida* sp. (below) and *Vitronura* sp. (bottom), and *Ceratophysella* sp. (Hypogastruridae) (right). (C) *Pogonognathellus* sp. (Tomoceridae) with disruptive scale pattern. (D) Juveniles of *Isotoma* sp. crowding together after hatching. (E) *Adranes coecus*, a clavigerite staphylinid beetle and closely associated inquiline of ants. This 2-mm beetle is perceived as a member of the colony due to secretions from specialized glands.

exude hemolymph through specialized body pores (pseudocelli) or have pre-existing deterrent chemicals externally or internally. Bitzer et al. (2004) described the attack by the rove beetle, *Stenus comma*, which has an extensible, sticky-tipped labium for catching prey, on a hypogastrurid. Following the attack (no harm to springtail), the beetle rubbed its labium on the substrate and regurgitated gut contents. The active chemicals were two isomers of benzoic acid on the springtail integument. Predacious mites attacking *Neanura muscorum* (Neanuridae) fed only momentarily or not at all, backing off and exhibiting enhanced mouthpart cleaning (Messer et al. 1999). Four different compounds presumably in the hemolymph were implicated in this deterrence. The hemolymph of another neanurid, *Brasilimeria assu*, was collected following reflex bleeding and the hemolymph was analyzed; it contained 32 compounds of several different classes, including benzyl benzoate, an ingredient in insect repellents (Zeppelini et al. 2019). Beetles rubbed with secretions and hemolymph exuded from the pseudocelli of the onychiurid *Tetradontophora bielanensis* exhibited disorientation and exaggerated mouthpart cleaning (Dettner et al. 1996). Fluids from the pseudocelli of *Onychiurus* spp. can paralyze predacious mites.

Chemical defense and mimicry may be closely linked. Fig. 21B shows several Collembola of two different families, Neanuridae and Hypogastruridae, in four separate genera. All four species are roughly sympatric geographically. Both families have species that have been shown to produce repellent chemicals. Strikingly, all four have the same basic color scheme of a white thorax and dark body. This contrasting pattern could be warning coloration for four unpalatable hosts, a potential example of Müllerian mimicry among Collembola.

Isotoma species are large (3 mm) springtails. In culture they lay clusters of eggs that hatch nearly simultaneously. These first-stage juveniles do not feed; instead, they cluster tightly together with their heads down and abdomens pointing outward (Fig. 21D). After about 2 weeks, individuals begin to leave the group, feed and develop. This grouping appears to be a defensive approach as the mouthparts and other organs of these juveniles mature. Interestingly, each individual has four small horns near the posterior end, which may serve as a deterrent to small predators. In the field, females might be more likely to lay egg clusters in a hole where the hatchlings would not be exposed so much.

Some soil-dwelling arthropods want to be friends with their potential enemies. The clavigerate beetle (Staphylinidae) in Fig. 21E is an obligate commensal of ants. Its survival in an ant colony is dependent on chemicals produced in glands covered by the orange tufts of setae. These chemicals tell the ants that this beetle is one of them.

Apparent mimicry is widespread among insects as well as the spiders in Fig. 11. All of the small hymenopterans in Fig. 22 are functionally wingless unlike most of their relatives and they more or less resemble ants. However, ants are Hymenoptera as well, so one would expect a certain similarity of design. Bethyids, dryinids and rhopalosomatids (Fig. 22A, B, D, H) are capable of delivering a sting, as are many ant species, which would provide a real deterrent and reinforce a shape to be avoided; this would seem to be a case of Mullerian mimicry for the stinging Hymenoptera and Batesian mimicry for the rest.

Fig. 22 Possible mimicry. Many hymenopterous families include members that have given up flight for a life on the surface and in litter. Their general resemblance to ants is not surprising, given that ants are also Hymenoptera. However, the specimens in (A–E) do appear to show significant convergence to a more ant-like design. (A and B) Bethyidae. (C) Braconidae. (D) Dryinidae (*Gonatopus* sp.). (E) Pteromalidae. (F and G) Scelionidae. (H) Rhopalosomatidae (*Olixon* sp.). Arrows indicate vestigial wings.

Conclusion

Plant health, and indeed the health of the terrestrial biosphere, is dependent upon the efficient functioning of the soil detrital food web, which returns nutrients to the soil for reuse. Soil arthropods are among the critical biotic components that drive this vast engine of decomposition and renewal. Nearly all of the arthropods described in this work can be found easily in backyards, fields and forests. Flipping over rocks, looking on the underside of discarded boards or tapping pine cones in a pan to dislodge the inhabitants can reveal all kinds of tiny yet interesting creatures. A simple hand lens is all that is necessary to begin examining the biodiversity and behaviors of the many thousands of small arthropods that scurry around under our feet.

Acknowledgments

All uncredited images were made by the author, except for those that are acknowledged. For those images I am grateful to Gary Phillips, Adrian Smolis, Kelly Silas Parman, Joseph Berger and Matthew Bowser for the use of their images and especially Suzanne Allen, who gifted me the archives of the late Dr. Robert T. “Tommy” Allen. Fig. 13E is an image made by the late Dr. Mark Muegge while a student at the University of Tennessee. David E. Walter provided valuable advice on mites. I also owe a large debt to former graduate students Cindy Williver Bilbrey, Kelly Felderhoff Oten, Matthew Petersen, Gary Phillips, Nicholas Reynolds and Haley Shae Smith for their enthusiastic interest in all things small.

Abstract

A hallmark of the Phylum Nematoda is their exceptional abundance and ubiquitous presence in soil as microscopic fauna. Nematodes require free water for normal functioning, but many are capable of entering a cryptobiotic state when conditions turn unfavorable. Communities span several trophic positions within the soil food web, collectively contributing directly to the biogeochemistry of soils by regulating decomposition and nutrient cycling. Nematode communities serve as biological indicators of soil health because they respond predictably to land-management practices. Valuing nematode communities as biological indicators of soil condition represents a tremendous shift in emphasis in the science of nematology that historically focused on plant-parasitic nematodes.

Key points

- Nematodes are the most abundant multicellular animals in the planet.
- Nematodes have colonized nearly every habitat on earth.
- Nematodes can exist in extreme environmental conditions.
- Parasitic nematodes can be lethal to plants and animals.
- Numerous ecosystem services are provided by nematodes but the extent and significance of these ecosystem services is yet to be determined.

Introduction – Life in a soil pore

Few people are aware of the most numerous of all soil-dwelling animals, the nematodes. These minute, unsegmented roundworms are actually aquatic organisms, inhabiting water films (1–5 μm thick) that coat and surround soil particles. This chapter focuses on nematodes that typically complete their entire life cycle within terrestrial soils or within plant roots. Numerous parasites of vertebrates have soil dwelling stages, but their development is dependent on entering an appropriate host species. Vertebrate nematode parasites include hookworms, intestinal roundworms, pinworms, whipworms, and other serious pests of humans and domesticated animals (Maggenti, 1981). Information about vertebrate parasites is readily found in textbooks of parasitology (Roberts et al., 2013). Their size, typically 0.40–1.0 mm in length, is ideal for navigating the porous matrix of soil. Although fully functional within a water film, they are ultimately bounded by soil structure, restricted in movement within soil pores less than 30 μm diameter. Nematodes are simple organisms (Fig. 1). Comprised of approximately 1000 somatic cells in the adult stage, these worm-like organisms are an example of functional and anatomical economy. Lacking eyes, appendages, and true segmentation, nematodes use mechanosensory and chemosensory neurons embedded in the cuticle to orient and respond to a wide range of environmental stimuli. At the nematode's anterior end is a cirlet of sensilla arranged around an oral opening (Fig. 2). These sensilla, including two larger, laterally placed chemosensory organs called 'amphids,' detect subtle chemical gradients, providing directional information to the nematode (Fig. 3). Plant-feeding nematodes respond to slight variations in CO_2 and root exudates. A positive chemosensory signal initiates a snake-like sinuous movement characteristic of most nematodes, created by longitudinal body muscles working in opposition to a hydrostatic skeleton. Directional movement more than a few centimeters per day is unlikely in the soil environment. Once they contact the root surface, plant-feeding nematodes will probe with their stylet, a hollow, protrusible, hypodermic needle-like feeding tube (Fig. 4A). Some plant-feeding nematodes will feed externally on the root surface, using this stylet to puncture cells, withdrawing the cytoplasmic contents. Others will penetrate the root and establish permanent feeding sites within the root cortex, or migrate cell-to-cell, leaving a trail of damaged necrotic tissue.

Free-living nematodes also occupy the interstitial spaces in soil. Unlike the plant-feeders, free-living nematodes are seldom sedentary, continually moving to feed on a diverse array of food, including bacteria, algae, fungi, protozoa, small invertebrates, and

other nematodes. They use the same set of sensilla to track their food source; however, their feeding structures are modified to suit their meal (Freckman and Baldwin, 1990). Bacterial-feeders (bacterivores) graze using a relatively simple tubular mouthpart, although the cuticle surrounding the oral opening may be modified elaborately to direct food toward the stoma (Fig. 5). Predators may be adorned with 'teeth,' used to puncture or shred the integument of various invertebrates (Fig. 6). Fungal-feeders (fungivores) and omnivores have a stylet similar in appearance to that of plant-feeders, distinguished by the lack of stylet 'knobs,' points of muscle attachment for stylet protrusion (Fig. 4B).

Early observations of nematodes by light microscopy led scientists to refer to nematodes as a 'tube within a tube.' Food entering the nematode is channeled quickly into a tubular pharynx and then passed into an intestine that comprises the bulk of the body cavity. Waste products are eliminated through a posterior ventral anus. There is no circulatory or respiratory system within the nematode. In addition to the alimentary system, the reproductive system is a conspicuous feature in the adult nematode (Fig. 7). Females and hermaphrodites are characterized by a branched genital system, which produces eggs that exit the body via a ventral genital opening in the body wall. Males possess a spicule, a cuticularized, protrusible modification of the genital system that guides sperm into the female for internal fertilization (Fig. 8). Many nematodes reproduce by amphimixis, but parthenogenesis and self-fertilizing hermaphroditism are also common among species. Regardless of mode of reproduction, nematodes are prolific animals. Some species complete a lifecycle of 3 or 4 days. Others require several months to go from egg to egg-laying female. *Meloidogyne* spp., an economically important group of plant parasites, will typically begin to produce eggs within 3 weeks of hatching; each female is capable of producing hundreds of eggs during an adult life.

Nematode distribution and abundance

The hallmark of Phylum Nematoda is the exceptional abundance and ubiquitous presence of nematodes (Table 1). It is a challenging exercise to identify a habitat not occupied by a diverse community of nematodes. Consider the dry valleys of Antarctica, i.e., so extreme environment that it is thought to provide the bare minimum for sustaining life on earth. There, in McMurdo Dry Valleys, four nematode species occupy the top levels in the soil food chain, three bacterivores and a fourth species, *Eudorylaimus antarcticus*, an omnivore that may feed on the two bacterivorous species (Freckman and Virginia, 1997). Soils of the high Arctic are populated so heavily with nematodes that biologists have searched for explanations for an Arctic nematode biodiversity that exceeds that of the humid tropics. Temperate grasslands appear to sustain the greatest levels of diversity and abundance in the phylum (Todd et al., 2006). On the Konza Prairie, one of the last remaining large stands of true tallgrass prairie in North America, each handful of soil is likely to contain 50–100 different nematode species. An estimated 1.5 million nematodes can be extracted from a square meter of soil, just within the surface 10 cm. Some researchers have considered the plant-feeding or herbivorous species as ‘belowground buffalo,’ referring to their impact as grazers of plant roots. Nearly all researchers agree that the approximately 25,000 described species of nematodes represent a small percentage of the species that actually exist in nature (van den Hoogen et al., 2019).

Finding agreement on those factors responsible for extraordinary nematode abundance and diversity is not so simple. Clearly, the evolutionary age of nematodes has provided considerable time for nematode diversification. Recent molecular studies indicate that the roots of the nematode evolutionary tree are hundreds of millions of years older than the corresponding tree for insects. Marine nematodes, which inhabit even the deepest ocean floors, have a nucleotide diversity that suggests nematodes flourished before life colonized land. The same nematode survival mechanisms that allowed them to be among the first colonizers of land most likely contribute to a competitive advantage in current-day harsh environments (Wharton, 2003).

Physiology

Although nematodes depend on water films for normal functioning, under harsh conditions such as freezing or drying many nematodes are capable of entering a cryptobiotic state, essentially a reversible state of suspended animation until favorable conditions return (Perry and Wright, 1998). Anhydrobiotic success, the ability to withstand the lack of moisture, depends on a slow rate of dehydration, rapid decline in cuticle permeability, and accumulation of compounds such as trehalose and glycerol to stabilize phospholipids and proteins. Species including *Acroboloides* spp., *Aphelenchus avenae*, and *Scutellonema brachyurum* start to enter anhydrobiosis by coiling at gravimetric water contents of 3.7% (–300 kPa), 9% (–30 kPa), and 15% (–10 kPa), respectively. It is unknown how long nematodes may persist in this state and still survive hydration. Specimens of the wheat gall nematode *Anguina tritici* have been revived after more than 30 years in anhydrobiosis.

Nematodes are not alone among invertebrates in their ability to enter a cryptobiotic state. Therefore, additional clues to their successful colonization of soil are found in their physiological versatility. Physiological adaptations have allowed nematodes to invade habitats in which few other animals can survive and avoid interspecific competition and many environmental selection pressures. Nematodes are capable of regulating their uptake of oxygen over a wide range of partial pressures from 100 to 5%. When oxygen falls below 5%, nematodes convert their use of energy reserves. For example, *Aphelenchus avenae* uses reserves of neutral lipids under aerobic conditions and glycogen under anaerobic conditions. Not only does a hydrostatic skeleton facilitate movement, but also an ability to expand or contract body size in response to gradual changes in concentration of solutions containing sodium, calcium, magnesium, or potassium ions. The adjustment process, osmoregulation, is possible by modifying the permeability of their cuticle. Furthermore, nematodes can tolerate a wide pH range, with some species capable of withstanding strong acids or bases (pH 1.6–11.0). Nematode tolerance for temperature is equally remarkable. In hot springs, nematodes live at temperatures as high as or higher than any other Metazoa. *Aphelenchoides parietinus*, a cosmopolitan species, has been reported from 58 °C springs in Chile and 61 °C springs in New Zealand. Moreover, nematode species recently discovered in Mono Lake, California can withstand 500× the human lethal dose of arsenic (Shih et al., 2019).

Ecology

Although nematodes have adapted mechanisms to survive extremities of climate, their activity is stimulated by the return of more moderate conditions. For example, communities of nematodes are revived after rain in desert soils or after a relatively warm period in soils of polar regions. Species are found interacting with other organisms in a variety of occupations including competitor, opportunist, parasite, host, predator, or prey. As a competitor, nematodes rival protozoa for access to bacterial food sources. However, differences in size and generation time can alleviate competition by specializing on microhabitats fine-tuned to minute spatial and temporal scales. As opportunists, nematode species are phoretically transported by insects, adhering to their bodies, providing an opportunity to reach food sources at a longer distance than they would be capable of reaching alone. For example, Psychodidae flies carry nematodes to fermenting organic matter; dung beetles carry nematodes to fresh dung; and Scolytidae bark beetles transport Tylenchida and Rhabditida to their tunnels, where they feed on bacteria and fungi. Nematodes that are parasites of plants include both specialists and generalists. Host ranges may extend to hundreds of plant species or be restricted to a single plant variety. Some nematodes specialize in precise feeding sites along the root. Plant-parasitic nematodes affect primary productivity of plants by altering uptake of water and nutrients. These abnormalities may result from changes in root morphology and/or physiology resulting in reduced productivity. Other nematodes infect insects, killing them within 48 h by releasing insect-pathogenic bacteria into the insect. The insect host dies from the bacterial infection, and nematodes feed on the bacteria and develop and reproduce inside the insect cadaver. In this case, the nematode and bacteria have a mutualistic association. Sometimes, a nematode finds itself in a role reversal, becoming the host or target of fungi specialized for trapping nematodes, using constricting rings, sticky knobs, or hyphal nets. Being in the middle of a food chain, nematodes eventually become prey to higher-order consumers. Nematodes provide a portion of the diet for many kinds of small soil arthropods. For example, a symphylan can hold seven large nematodes in its gut at one time. In 1 day, a mite may consume two large nematodes or several smaller nematodes.

Genetic diversity, nematode abundance, and the variety of niches occupied by nematodes has led to the assessment of nematode communities as a means of making predictions about past or present soil conditions. The species composition and relative nematode abundance of species comprising a nematode community allow nematodes to serve as biological indicators for soil disturbance as well as 'soil health.'

Monitoring

Nematodes contribute directly to biogeochemistry of soils by regulating processes such as organic matter decomposition and nutrient cycling (Freckman, 1988; Ingham et al., 1985). Nematodes do not feed on decaying organic matter directly, but on bacteria, fungi, algae, and actinobacteria that colonize and decompose decaying plant and animal debris. Indirectly, nematodes control availability of nutrients by regulating the abundance or activity of these organisms, releasing nitrogen and phosphorus from microbes they digest, immobilizing nutrients in their live tissues, and excreting excess nitrogen as ammonium. Under field conditions, bacterivorous and predatory nematodes contribute 8–19% of nitrogen mineralization in conventional and integrated farming systems, respectively (Neher et al., 2012).

Nematode community structure and function are known to change in response to land-management practices such as nutrient enrichment through fertilization by organic or inorganic nitrogen, cultivation, liming, drainage, plant community composition and age, and toxic substances such as heavy metals, pesticides, and polycyclic aromatic hydrocarbons (Neher, 2010). Disturbance can affect the survival of individuals directly, or indirectly by changing resource levels. For example, a larger ratio of fungivorous to bacterivorous nematodes suggests less effect of cultivation than does a smaller ratio. Any disturbance that results in compaction reduces soil porosity, and the numbers of relatively large-sized nematodes. General biocides such as methyl bromide can nearly eliminate nematodes, returning the ecological succession of soil communities to that assembling a depauperate soil matrix. Although recovery occurs eventually, abundance and diversity of nematode communities may take years to achieve prefumigation levels. Alternatively, some herbicides affect nematodes indirectly by reducing vegetation and smaller additions of organic matter to soil.

The composition of nematode communities may reflect the frequency of disturbance to soil, whether the disturbance is primarily physical and/or chemical in origin (Neher, 2010). This concept is based on the principle that different species have contrasting levels of sensitivity or tolerance to stress because of unique survival and/or reproductive traits. Smaller values of an index that integrates relative abundance of species within each sensitivity/tolerance class are indicative of a more disturbed environment, and larger values may indicate a less-disturbed environment. Ideally, indicators of soil health would correspond with ecological processes occurring in soil. Because initial experiments have been correlative in nature, it is too soon to claim such an association with great confidence.

The concept of nematodes as indicators of soil condition and their predictive use in soil management represents a tremendous shift in emphasis in the science of nematology (Beaumelle et al., 2021). Formerly a science focused on the control of parasitic and harmful species, now nematodes are an integral and potentially useful component of soil systems. Considering this new perspective, it is likely that the study of nematodes will contribute significantly to our understanding of biological processes in the soil.

Abstract

Earthworms are considered to be ‘ecosystem engineers’ because their impact on the soil environment significantly influence the activities of other soil organisms (plants and microorganisms). Their pivotal role in ecosystem functioning translates into the delivery of essential ecosystem services including plant growth, soil structure, nutrient cycling, water and climate regulation and cultural services. Despite the extensive research into their taxonomy and ecology, there is substantial lack of detailed knowledge on the potential effects of current and future environmental threats on their distribution and performance of vital soil functions. Actions to protect these organisms are needed to effectively conserve our soils.

Glossary

Ecological categories Species groupings based on morphological, ecological and feeding characteristics defined by Bouché (1977) and that include epigeic, anecic, and endogeics together with some intermediate categories.

Cast Fecal material egested by earthworms that is deposited in the burrows or at the soil surface; they can adopt different shapes, including pellet cast, turret cast and mass cast.

Drilodefensins Unique metabolites that counteract the inhibitory effects of polyphenols on earthworm gut enzymes.

Drilosphere The area of soil directly affected by earthworm burrowing activities; it typically refers to the thin (few millimeters thick) layer around the burrows.

Midden The mound of cast, litter and organic materials accumulated by an anecic earthworm at the burrow entrance.

Rhizosphere The area immediately surrounding the plant roots of intense biological activity attracted by root exudates.

Key points

- Earthworms are considered to be “ecosystem engineers” because they create, maintain and modify the soil environment and thus affect the activities of other soil organisms (either directly or indirectly).
- Their high taxonomical and functional diversity enables them to exploit different trophic niches and withstand adverse environmental conditions; however, perturbations in soil abiotic and biotic properties can have profound alterations on their community structure and activities.
- They are bioturbating agents as they create burrows, incorporate litter along the soil profile, mix soil and produce casts; this makes them one of the most important decomposers in soils and responsible for the delivery of provisioning, supporting, regulating and cultural ecosystem services.
- Despite their pivotal role in ecosystem functioning, research is biased toward their ecology and the most economically beneficial services (primary productivity, vermicomposting, fish bait).
- Importantly, they are excluded from soil protection regulations and the threatened status of the majority of the earthworm species is currently unknown.

Introduction

Earthworms are terrestrial segmented animals (phylum Annelida) which at maturity develop a “clitellum” (the glandular swelling on several segments in the anterior half of the body that forms the cocoons or egg capsules); this is why they are included in the class Clitellata. Because each body segment bears a low number of short setae, they are placed in subclass Oligochaeta (usually eight on

Fig. 1 *Dendrodrilus rubidus*, a small size earthworm living in the upper layers of the soil. The two main types of seate arrangement: (i) octochaetine, eight seate on each segment (four pairs closely or distantly paired) and (ii) perichaetine, numerous setae forming a ring around each segment.

each segment (four pairs) = octochaetine arrangement, but those included in the Megascolecidae family can have more than 30 seate per segment (40–200 around the equator of each segment = perichaetine arrangement) (Fig. 1). Further subdivisions include order Haplotaxida and suborder Lumbricina that contains 38 families, of which Acanthodrilidae, Megascolecidae and Lumbricidae contains the highest number of species. Approximately 7000 of valid species have been described but it is estimated that there might be around 30,000 globally (Orgiazzi et al., 2016).

Their body size ranges from a few cm to 2–3 m in length, with most species fall into the interval of 5 to 15 cm. Therefore, according to the body size classification proposed by Swift et al. (1979), they are included in the macrofauna gross group. This includes those soil organisms whose body width is greater than 2 mm. Although the majority of the species are not very colorful (including some unpigmented worms), some tropical species exhibit bright colorations, stripped patterns and even glow in the dark (bioluminescent). This large variability in pigmentation can be attributed to their ecological behavior and hence, whether they spend most of the time in the deeper layers of the soil (pale in color) or make frequent incursions to the upper soil and litter layers and thereby, become more exposed to UV-light (darker coloration).

Environmental filters shaping their geographical range

Earthworms are distributed worldwide, except for the poles, with the greatest abundance and diversity found in the temperate areas (Phillips et al., 2019). This is due to the strong influence that climatic variables (namely temperature and precipitation regimes) have on their life cycle and activities, with extreme conditions (prolonged heat and drought, but also freezing temperatures) strongly affecting their abundances and the species composition of their communities. Despite these strong environmental filters, some species are known to exhibit high tolerance to adverse environmental conditions through specific physiological and behavioral adaptations. For example, by secreting cryoprotectant substances against freezing temperatures (Jørgensen et al., 2008) or by finding refuge in the deeper soil layers, such as in the case of *Megascolides australis*, a giant earthworm that is able to extend its burrow system deeper than 1.5 m (Kretzschmar and Aries, 1992). That is why changing climatic conditions may facilitate the invasion of earthworms at higher latitudes (Singh et al., 2020), with important implications for nutrient cycling. A study comparing earthworm-invaded and earthworm-free zones, in soil types that are representative of the boreal forest, showed that the invasion of non-native earthworms caused the thinning of the surface organic layer in most cases, and the development of a vermimull humus form (Lejoly et al., 2021).

In addition to climatic factors, soil properties also play an important role in determining community composition and species abundance. In particular, soil pH is a strong determinant of their habitat preferences, with most species benefiting from nearly neutral pH values (5.5–7.0). However, a few acido-tolerant species such as *Dendrobaena octaedra*, *Dendrodrilus rubidus* and *Lumbricus rubellus* can tolerate pH values between 4.0 and 5.5, and are often the main species colonizing forest soils and organic rich environments (e.g. acid grasslands, compost piles, etc.). Furthermore, clay content also seems to affect earthworm densities and

individual growth (Klok et al., 2007), possibly through changes in other soil properties, such as organic matter content and water retention.

Intensive agricultural practices also pose serious risks to earthworm survival. Soil compaction due to the use of heavy machinery, removal of the potential food sources (e.g. crop residues), excessive use of mineral fertilizers as well as agrochemicals, and plowing severely reduced their populations, causing the disappearance of the surface dwellers and larger burrower species and the majority of adult individuals (Briones and Schmidt, 2017). Land degradation through soil pollution (heavy metals, organic pollutants, microcystins, antibiotics) can also be harmful to certain earthworm species, whereas others show a high degree of tolerance by accumulating high amounts of these toxic substances in their tissues (bioaccumulation) or by exhibiting cleansing mechanisms via hydrolysis and oxidation followed by conjugation (Katagi and Ose, 2015).

In view of this, it is clear that current drivers of ecosystem degradation worldwide, particularly climate and land use changes, are expected to have severe effects on earthworm communities across the globe, which could have cascading effects on the other organisms (both above- and below-ground) with which earthworms interact.

Functional diversity: Habitat and dietary requirements

Earthworms can be differentiated according to their external morphology, burrowing behavior and feeding habits. This led Bouché (1977) to classify them into three ecological categories: (i) the small sized and heavily pigmented epigeic worms colonize the litter layer and top soil horizons, where they can consume fresh organic substrates; (ii) the larger anecic are darker in color and build more or less vertical burrows to feed on the soil surface; (iii) the medium sized endogeic worms are usually unpigmented or with a light coloration and construct branching sub- and horizontal burrows in the mineral soil horizons where they feed on more recalcitrant sources (Fig. 2). Despite not being universally accepted (e.g. Lavelle, 1979), this functional classification is nevertheless widely used among earthworm ecologists because it provides more valuable information about their role in ecosystem functioning than species assemblages (Briones, 2014).

Indeed, these three groups show different rates of food consumption, assimilation and egestion, although previous observations show a high variability depending on the substrate quality, earthworm activity and experimental conditions (Curry and Schmidt, 2007). Egestion rates are also variable and a reflection of their feeding preference. For example, the endogeic species *Aporrectodea caliginosa* can egest 349 mg (dry matter) of feces per gram of worm (fresh weight, fwt) daily, whereas *Lumbricus terrestris* (anecic) has a daily egestion rate of 165 mg dry weight (dwt) feces per gram of worm (fwt) (Taylor and Taylor, 2014). The degree to which the ingested material is digested is influenced by their enzymatic capabilities (including a wide array of enzymes such as

Fig. 2 Earthworms can be ecologically differentiated according to their external morphology, burrowing behavior and feeding habits into three groups (Bouché, 1977): (i) epigeic earthworms are small sized and their burrowing and casting activities concentrate in the top soil horizons where they can consume fresh organic substrates; (ii) anecic earthworms are larger in size and build more or less vertical burrows to feed and defecate on the soil surface; (iii) endogeic earthworms are medium sized and construct branching sub- and horizontal burrows in the mineral soil horizons where they feed on more recalcitrant sources.

phenol-oxidase, catalase, protease, cellulase, glycosidase, phosphatase, among others), which ultimately rely on the microorganisms living in their gut or present in the ingested food. In the particular case of those species feeding on polyphenol-rich plant litter, such as in woodland soils, they make use of the unique surface-active metabolites in their gut called 'drilodefensins,' which act as biological surfactants to impede the precipitation of proteins by polyphenols (Liebeke et al., 2015).

These different strategies could represent mechanisms for avoiding competition for the same spatial and trophic resources, but also be a reflection of different adaptations to changes in the soil environment, such as droughts or winter freezing. Because the first protective barrier of earthworms is their tegument, differences in their body wall thickness across these functional groups have been linked to adaptations to specific soil habitats, allowing the use of the earthworm tegument for assigning species to certain ecological groups (Briones and Álvarez-Otero, 2018). According to these authors, not only do anecics have the thickest cuticle and epidermis compared with epigeics and endogeics, but also two types of anecic worms can be identified: (i) 'shelters' that live in permanent burrows (e.g. *Lumbricus terrestris*), and (ii) 'explorers' that build temporary burrows to feed at deeper layers and to find a shelter during those periods when they remain inactive awaiting for better environmental conditions (e.g. *Aporrectodea longa*). In support of this, morphological and functional differences between earthworm burrows produced by species belonging to the same ecological grouping have been observed with the help of X-ray tomography, a technique that has greatly increased our understanding earthworm bioturbation activities (e.g. Capowiez et al., 2015; Le Bayon et al., 2021). Thus, in contrast with Bouché's definitions, these categories are by no means exclusive and more research is needed for a better integration of the existing variability (Bottinelli et al., 2020).

Interactions with other soil organisms and aboveground vegetation

Different earthworm activities influence the diversity and population density of other organisms (both above- and below-ground) either directly or indirectly. For example, soil microorganisms (both fungi and bacteria) are food sources for earthworms; hence, their numbers in soils can be reduced when earthworms are present, but they can also be promoted through a priming effect after gut transit. Consequently, earthworms are able to change the microbial community composition in their area of influence, the so-called "drilosphere." It has been suggested that fungal spores are destroyed or inhibited by the conditions in their digestive system, but bacteria cells are stimulated because they can adapt to the anaerobic environment in the intestine (Don et al., 2008). Accordingly, more Proteobacteria, Actinobacteria, Firmicutes, Acidobacteria, Planctomycetes, Bacteroidetes, Nitrospirae, and Chloroflexi have been observed in the presence of earthworms (Medina-Sauza et al., 2019).

In contrast, although plant roots are also ingested while working through the soil, there is little evidence that live plant material greatly contributes to earthworm nutrition. Instead they seem to be more attracted toward root exudates (Curry and Schmidt, 2007). In relation to this, $^{13}\text{CO}_2$ pulse labelling experiments have shown that although earthworms assimilate recently photosynthesized carbon, it is not their primary food source (Ostle et al., 2007). However, their role as granivores and seedling herbivores has been demonstrated in laboratory experiments (Eisenhauer et al., 2010) indicating that these organisms can indeed digest seeds. This together with the fact they can also passively disperse seeds, spores and viable propagules, it is clear that they also have an important role in shaping plant communities. In addition, earthworms appear to modify plant growth, development and defense through the emission of signal molecules (Puga-Freitas et al., 2012). For example, presence of earthworms can affect plant photosynthetic activity (measured as increased chlorophyll leaf concentration) and lead to higher aboveground biomass and tolerance to parasites (Blouin et al., 2005).

Tunnelling the soil is another way by which earthworms modify the soil habitat. They create porous space that facilitates soil colonization by aerobic microorganisms (specifically Gram-negative bacteria and fungi; Banfield et al., 2017) and provide channels for roots, which can extend their network without investing mechanical energy to penetrate the soil (Canellas et al., 2002).

Finally, undigested materials deposited in their casts and burrow linings provide nutrients for microorganisms and plants. They are rich in nitrogen, either as ammonium that attracts microbes (Lavelle and Martin, 1992) or as a nitrate. Some plant species (e.g., *Brachypodium distachyon*) can take up as much as 20–30% of the nitrogen for their requirements by foraging N from 46 days old casts (Agapit et al., 2018). In particular, anecic species, which form permanent or semi-permanent burrows, tend accumulate organic and inorganic materials together with their casts around the burrow entrance (the so-called "middens") that are also a hotspot for microorganisms and can also function as an "external rumen" that aid them in the breakdown of the plant material.

Role of earthworms in the delivery of ecosystem services

Earthworms are responsible for the delivery of provisioning, supporting, regulating and cultural ecosystem services (Fig. 3). Although this research is biased toward the most economically beneficial services (such as crop productions and soil structure), substantial gaps of knowledge remain (Blouin et al., 2013).

The effects of earthworms on the provisioning of food for human and animal consumption has been intensively investigated both in the field and under laboratory conditions. After reviewing the data derived from staple crops (maize, rice and wheat), pastures, as well as many other food crops across the globe between 1910 and 2013, van Groenningen et al. (2014) found that, on average, earthworms led to a 25% increase in crop yield and a 23% increase in aboveground biomass. Five mechanisms have been identified as potential responsible for these positive effects of earthworms on plant growth (reviewed by Blouin et al., 2013): (i) increased soil

Fig. 3 Ecosystem services provided by earthworms can be both direct (by providing benefits that can be directly used) and indirect (through the interactions with plants and other organisms): (i) provision services (food, fresh water and raw materials); (ii) supporting services (soil formation, habitat sustenance); (iii) regulating services (hydrological services, climate regulation, disease and pest control); (iv) cultural services (natural capital).

nutrient availability due to acceleration of soil organic matter decomposition and mineralization; (ii) improved soil structure that increases water mobility and oxygen concentrations; (iii) biological control of potential pests and parasites; (iv) stimulation of the secretion of plant growth regulators by microorganisms; (v) enhancement of symbiotic relationships. An important component that drives many of these responses are earthworm casts (or vermicasts) that are deposited at the soil surface or on the walls of their burrows (Fig. 2). This cast material produced by earthworms is far more fertile than bulk soil in terms of cation exchange capacity, base saturation, total organic carbon, total phosphorus and total nitrogen concentrations, as well as for plant available pools of N and P (van Groenigen et al., 2019). As a result, earthworm casts not only enhance plant growth but also the germination and establishment of certain plant species (Clause et al., 2016), providing the basis for the profitable business of supplying vermicompost for agriculture and gardening activities worldwide (Fig. 3).

Supporting services by earthworms include soil formation and maintenance. Earthworms are important agents for the breakdown of primary minerals (chemical weathering) and organic materials (humus formation) as well as for pore and aggregate formation (Fig. 3). Their burrows and biopores are highly stable structures thanks to greater compaction at their walls, the fine texture of subsurface casts and the frequent secretion of biopolymers and mucus lining the burrows (Jegou et al., 2001; Ruiz et al., 2015). In addition, earthworm casts cement soil particles together in water-stable aggregates, which can represent 40–60% of the soil weight in the upper 15 cm of soil (Lavelle et al., 2020) and help to rebuild the soil. It has been estimated that, under favorable conditions, in temperate climates, they can deposit 50 t/ha annually of these biogenic aggregates, enough to form a layer from 5 to 25 mm thick layer (Bertrand et al., 2015). Indeed, the term “vermiform” was introduced in the US Soil Taxonomy to define a new type of soils with at least 50% or more of the A horizon and > 25% of the B horizon volume consisting of earthworm cast material and their biostructures (Feller et al., 2003). However, earthworm species that either compact or loosen the soil have also been

identified, with crucial implications for soil bulk density, porosity, water infiltration and soil erosion. Overall, more positive effects on soil formation and improvement of soil structure than negative ones have been described in the literature (Blouin et al., 2013).

Bioturbating activities by earthworms, including burrowing, litter incorporation and decomposition, soil mixing and aggregate formation, directly affect *regulating services* such as SOM turnover and C storage, nutrient cycling, water purification and flood control, and climate regulation (Fig. 3). While the accelerating effects of earthworms on organic matter decomposition, N mineralization and hydraulic properties appear to be undisputed (Blouin et al., 2013; Briones, 2021), their effects on C sequestration and greenhouse gas mitigation remain unresolved. Part of the problem is the difficulties in obtaining reliable measurements of the earthworm contribution to the dynamic transformations (mobilization vs. stabilization) of the basic nutrient elements (C and N) and their separation from other interactive factors (plant activities, interactions with microorganisms). Many studies have shown that earthworms induce C stabilization, for example by favoring the decomposition of leaf- over root-derived SOM, which contributes to the gradual accumulation of the latter fraction in soil (Angst et al., 2020). They also contribute to the formation of microaggregates and the integration of these into macroaggregates through stimulation of the microbial glue between the mineral particles and hence, not only they increase C stability but also its resilience against environmental perturbations (Angst et al., 2019). In contrast, several studies have suggested that earthworm activities increase greenhouse gas (GHG) emissions. Thus, in controlled experiments without plants, earthworms increased the emissions of N₂O by 42% and CO₂ by 33% (Lubbers et al., 2013), a finding that has been hotly disputed (e.g. Zhang et al., 2013). On the other hand, endogeic worms consistently reduced the impact of periodic flooding on CH₄ emissions from riparian soils (Kernecker et al., 2015). A more recent review concluded that physicochemical properties of soil, residue incorporation, species feeding strategies and the duration of the experiments modulate earthworm impacts on GHG emissions (Singh and Singh, 2019). Clearly, more field and long-term evidence is required to establish the direction and magnitude of these effects and to enable realistic extrapolations of the effects of earthworms on GHG balance.

Another important, although far less studied, regulating service provided by earthworms is the control on the populations of other organisms. One of the key aspects that have led to consider earthworms as “ecosystem engineers” is the fact that their biogenic structures (aggregates, burrows) serve as habitats for different species other than themselves (Lavelle et al., 1997). For example, the large amounts of bacterial and fungal decomposers in earthworm biopores are a clear indication that they represent hotspots of microbial activities (Banfield et al., 2017). In an agronomic context, the earthworm effects on pest suppression were confirmed by substantial reductions in the number of infested plants by parasitic nematodes (Blouin et al., 2005) and oomycetes (Lagerlöf et al., 2020), as well as enhanced resistance against herbivores (Xiao et al., 2018). This reduction in pest susceptibility and disease symptoms were attributed to both direct (consumption of the pathogenic organisms) and indirect effects (such as soil disturbance and improved plant fitness). For example, it has been shown that the presence of earthworms can increase the production of chemical defenses by 31% when plants are attacked by cell-feeders (thrips), resulting in an 81% increase in resistance against these plant-sucking insects (Xiao et al., 2018).

Although far less studied, *cultural services* provided by earthworms have been long acknowledged and include a variety of benefits to humans (Fig. 3), from a source of protein for some tribal communities in the Amazon (Moreno and Paoletti, 2004) to medicinal products (Cooper et al., 2012). Their burial activities can be seen either as positive (i.e. preserving archeological remains; Canti, 2003) as well as negative (i.e. destruction of heritage sites; Motiejūnaitė et al., 2019), but exploitation for stratigraphic interpretation is only minor (Canti, 2003). In addition, earthworms are commonly represented in art, literature, stamps and crafts (Motiejūnaitė et al., 2019) and a theme in cultural and social celebrations such as the “Worm Charming” events in some localities in England. Much more appreciated is their value as gardeners’ friends and as fish bait, and the commercial value of growing earthworms to be sold for vermicomposting and as bait for fish stores, animal growers (frogs, poultry, game birds) has become a very profitable business in several parts of the world. For example, in North America one pound of *Lumbricus rubellus* sells for around \$15–30 on the commercial market depending on the supplier, and in Ontario (Canada) the supply of *L. terrestris* has become the most lucrative business in the region with farmers leasing land to worm-pickers for over CA\$1000 per year (Steckley, 2020).

Conclusion

The crucial role of earthworms as “nature’s plow,” increasing soil fertility and helping plants to grow, has been recognized from the time of Charles Darwin. However, despite their quantifiable benefits for soil functioning, no specific regulation has been formulated to protect these essential ecosystem engineers (either nationally or internationally) and the potential threatened status of most of the earthworm species is currently unknown. More research is needed to fill the current knowledge gaps on their physiological responses to environmental threats, habitat requirements and restrictions, variability in feeding strategies and their complex interactions with their soil physical and chemical environment and with other organisms to ensure their protection and the continuously delivery of the ecosystem services they provide.

Abstract

Biofilms are recognized as essential habitats for the majority of bacterial and archaeal life on Earth. These microbial assemblages are hotspots for trophic, genetic, and inter- and intra-species communication. The sessile lifestyle confers survival advantages to biofilm inhabitants under harsh environmental conditions. As one of the major microbial biomes, soil provides a huge internal surface-area for biofilm formation. However, due to the opaque nature and spatio-temporal heterogeneity of soil system, the distribution of biofilms in this medium remains obscure. In this chapter, we present fundamental criteria and context for understanding biofilms and their ecological importance in soil.

Key points

- Review of the current state of knowledge regarding soil biofilm concepts.
- Summary of the ecological functions of biofilms.
- Discussion of the challenges and future opportunities for soil biofilm research.

Introduction

It is widely accepted that most naturally occurring microbes exist in a biofilm at some stages (if not all) of their lifecycle. The ubiquity of biofilms in natural, industrial and clinical environments was initially described by Costerton et al. (1987). It has been estimated that 20–80% of cells on Earth currently inhabit biofilms. More than 95% of bacteria and archaea on Earth live in the ‘big five’ habitats: deep oceanic subsurface (33.3%), upper oceanic sediment (4.2%), deep continental subsurface (25.0%), soil (25.0%) and oceans (8.3%). Microbial life tends to attach to solid surfaces, where it subsequently begins the processes of biofilm formation (Flemming and Wurtz, 2019). As one of the ‘big five’ habitats, soil offers a huge internal surface area and hosts approximately one quarter of all microorganisms on Earth. Microscopic observations show that most soil microbes are attached on soil mineral surfaces and are immersed in thin films (Fig. 1). Microbial cells are known to attach to surfaces in soil pores and develop multicellular aggregates and many believe that biofilms are the dominant growth form in soil (Flemming and Wurtz, 2019). Meanwhile, recent experimental evidence revealed that soil biofilm formation is a dynamic strategy for soil microbes which responds to labile carbon input (Redmile-Gordon et al., 2020; Redmile-Gordon et al., 2015; Wu et al., 2019). This concept will be discussed in detail in the following sections.

The evolving concepts of soil biofilm

Given the high density of attached microbial cells in soil, the term ‘soil biofilm’ was generally accepted for describing the lifestyle of soil microorganisms within their associated polymeric matrices. In comparison to other natural or industrial habitats, the volume of space available for biofilm development in soil is restricted by mineral fragments and other constituents. Uncertainties in the spatial distributions of biofilm-dwelling microorganisms have ignited a debate over their existence (Bar-On and Milo, 2019; Baveye, 2020). However, microscopic observations of soil show that multicellular microbial aggregates exist in soil, but as patchy biofilms (Fig. 1) rather than the thick and uniform biofilms that are imagined in wastewater treatment and biofouling processes (Eickhorst and Tippkötter, 2008; Flemming et al., 2021; Nunan et al., 2003; Watteau and Villemin, 2018).

The debates over biofilms require a clarification on related definitions. In the terminology of biomaterials, biofilms are aggregates of microorganisms where cells are embedded in a matrix of extracellular polymeric substances (EPS)

Fig. 1 Microscopy images of soil biofilms. Calcofluor White-stained biofilms in a surface sandy silt loam (A) (Nunan et al., 2003). Biofilm colonies were heterogeneously distributed and separated by uncolonized regions. FISH-stained biofilms in an undisturbed sandy soil (B) (Eickhorst and Tippkötter, 2008). The biofilm cells were visualized with the eubacterial probe Eub338-FITC. The distribution of biofilms in mineral grains (left panel) and soil aggregates (right panel) (C) (Gutiérrez Castorena et al., 2016). The numbers represent the bacterial population size of individual biofilms. Biofilms in an artificial soil (D) (Wu et al., 2019). Soil biofilm formation induced the development of micro-meter sized aggregates. Biofilm cells embedded in self-produced EPS matrix in a calcic soil (E) (Watteau and Villemin, 2018). (Vert et al., 2012). Based on this, and also the definitions from other disciplines, soil biofilms were defined as *aggregates of microbes connected by EPS* (Redmile-Gordon et al., 2014). However, there are no existing criteria to define a soil biofilm either for the minimum number of cells, or the size of the EPS matrix.

Interestingly, a diagnostic criterion of clinical biofilms was established in the context of human disease. Apart from the multicellular structure, it is based mainly on enhanced resistance to antibiotics, and persistence against host defenses (Hall-Stoodley and Stoodley, 2009). This raises the question as to whether small biofilms in soil retain the innate resistance seen in mature biofilms. The reduced susceptibility of biofilm cells to antimicrobial agents and environmental stresses has been attributed to physically restricted diffusion rates and chemical interactions between solutes and EPS. Although mature, thick biofilms were initially believed to be a prerequisite for biofilm resistance, thin biofilms (5–10 μm) also exhibit altered physiology, including increased microbial resistance to heavy metals (Teitzel and Parsek, 2003). Therefore, soil biofilms of similar size impart resistance to antimicrobial stresses and exhibit biofilm emergent properties, further differentiating them functionally from their free-living counterparts. Therefore, it may be useful to think of biofilms as *aggregated microbial cells embedded in a matrix of EPS which exhibit emergent properties absent in free-living cells* (Flemming et al., 2021). This view should help facilitate much needed progress in this area.

Nonetheless, biofilms remain a fundamental form of microbial life on Earth with phenotypic expression of prokaryotes being highly dependent on the stage of life-cycle, e.g., biofilm forming vs. free-living (Bar-On and Milo, 2019). The triggers or 'cues' for changes in life-cycle are largely environmental, but include bacterial density, quality of carbon in the soil or growing medium and environmental stresses (Redmile-Gordon et al., 2015). Knowing the proportion of soil microbial biomass that exists in a biofilm phase of growth at any given time, will help to improve predictions related to soil biogeochemistry and the soil physical properties (Cai et al., 2019).

The concept of 'microbial biomass carbon' specifically relates to cell carbon content, and accordingly is measured as 'biomass carbon'. These cells can be either (i) free-living (planktonic or sessile), or (ii) members of a biofilm. If one adopts a working definition of *aggregated microbial cells in a matrix of EPS* during visual investigations of bulk soil, a large proportion of the soil microbial biomass may exist independently of biofilms. Although most soil bacterial isolates form biofilms in rich media, only about 0.1–2% of the microbial biomass in non-rhizosphere soils has sufficient carbon to grow (Blagodatskaya and Kuzyakov, 2013). Micrographs reveal that the spatio-temporal distribution of soil microorganisms is highly heterogeneous. Only 0.000001% of internal soil surfaces are colonized by microbes (Young and Crawford, 2004), while about 1–0.0001% cells have a neighbor within an 'interaction distance' of approximately 20 μm (Gutiérrez Castorena et al., 2016; Nunan et al., 2003). Therefore, in most bulk soils, microorganisms occupy a relatively vast expanse, with the fraction residing in biofilms potentially being very small and restricted to specific carbon-rich interfaces (Fig. 2).

Fig. 2 Schematic diagram of increases in active microbial biomass with the capacity to form biofilms in response to inputs of photosynthate-C. Dormant microorganisms can be activated by an influx of labile substrates (process 1). Subsequently active microbes assimilate labile C into microbial biomass and extracellular polymeric substances (EPS) (process 2). Continued microbial growth and EPS production forms a biofilm. The micrometer sized films exhibit an extended phenotype, providing a favorable environment for intercellular interactions and metabolic activity, while protecting against heavy metals, desiccation, and predation.

The EPS production in soil

As EPS is a crucial component of biofilms, its production is a prerequisite for their formation in soil. Soil microorganisms process organic matter and synthesize metabolites, which can be stored extracellularly as EPS. When nutrients are depleted, microorganisms can selectively use certain components in EPS as nutrient source to survive. For example, in the absence of carbon sources, cyanobacteria secrete polypeptidase and cellulase to hydrolyze and assimilate the self-produced organic carbon (Stuart et al., 2016). Soil EPS can also serve as a communal growth substrate for microorganisms in soil. *Actinobacteria* and *Proteobacteria* widely distributed in soil can use homogeneous polysaccharides in EPS, such as cellulose, as carbon sources, while microorganisms such as *Planctomycetes* and *Armatimonadetes* selectively decompose and utilize the heteropolysaccharides (Wang et al., 2015). Moreover, microorganisms can also obtain inorganic nutrients such as nitrogen and phosphorus by decomposing the proteins and DNA in EPS (Bohórquez et al., 2017).

The secreted EPS is mainly distributed on the surface of cells and minerals, providing a feasible living environment for soil microorganisms (Buckeridge et al., 2022; Zhang et al., 2021). The association of EPS with soil minerals can significantly reduce its bioavailability via various physical and chemical protection mechanisms (Mikutta et al., 2011). The protective effect makes it possible for EPS to persist in the soil and eventually form stable soil organic matter to expand the soil carbon pool (Buckeridge et al., 2022). Thus, the synthesis and decomposition of EPS essentially contribute to the turnover of soil organic carbon. However, most investigations on soil EPS are based on the cultivation of pure bacteria in the laboratory, and little is known about the conversion efficiency, EPS products and corresponding degradation process in the soil environment. More efforts need to be devoted to elucidate the fate of these exopolymers in soil.

The production of the EPS matrix and maintenance of biofilm structural integrity requires considerable investments of energy (Flemming et al., 2016). EPS typically accounts only for 2–15% of soil organic matter (Redmile-Gordon et al., 2020), but under copiotrophic conditions, soil microorganisms can store additional carbon as EPS (Redmile-Gordon et al., 2015; Wu et al., 2019). Supporting this, EPS are transient bonding agents and are produced rapidly in response to land-use change and correlated with soil structural improvements (Redmile-Gordon et al., 2020). Microorganisms assimilate nutrients and incorporate part of soil organic matter as extracellular polymers (Liang et al., 2017). The EPS synthetic efficiency is influenced by microbial species, growth status, nutrient types and other biotic and abiotic factors. Analyses of the EPS synthetic efficiency of 38 soil isolates showed that most had a higher synthetic efficiency for EPS than for the synthesis of cellular components (Fernandes Jr. et al., 2011). The synthesis efficiency of EPS in natural soil ($\mu\text{g EPS nmol}^{-1} \text{ATP}$) was found to be substantially improved when inorganic N was not available in excess (Redmile-Gordon et al., 2020).

Different organic carbon sources affect EPS synthetic pathways according to limits of the metabolic production of exopolymer precursors (Flemming et al., 2016). In addition, the production of EPS also depends on other aspects of the soil environment, including temperature, pH and the availability of nutrients such as carbon, nitrogen and phosphorus. For example, compared with low molecular weight organic acids (formic acid, acetic acid), microorganisms can secrete more exopolysaccharides when using glucose as a carbon source (Li and Yang, 2007). The substrate composition was also found to influence soil EPS production. When the substrate C:N ratio decreased from 20 to 4, the carbohydrate content in loosely bound EPS decreased by 200%, while the extracellular protein content increased by 300% (Ye et al., 2011). It suggested that a low C:N ratio enhanced the synthesis and secretion of extracellular protein (Ye et al., 2011). Conversely, in soil containing a substantial organic matter pool, an increased C:N ratio of inputs, caused both the production of extracellular polysaccharide and protein to be significantly enhanced (Redmile-Gordon et al., 2015). Therefore, EPS production would seem to interact with organic matter availability but is a microbial survival strategy that responds to the stoichiometric ratio of labile inputs (Redmile-Gordon et al., 2015). With the same C:N ratio, sufficient nutrient supply was the prerequisite for the formation of soil biofilm (Wu et al., 2019). A 10-times increase in carbon and nitrogen contents resulted in a decreased microbial biomass growth and a 14.2-fold increase in EPS production, which triggered the formation of soil microaggregates (Wu et al., 2019).

Intrinsically, EPS is a key element in soil biofilms. High organic carbon input stimulates soil EPS production. The increased substrate availability activates dormant cells to initiate biofilm formation, and habitats such as the rhizosphere and detritosphere are hotspots for the formation of dense microbial assemblages (Gutiérrez Castorena et al., 2016; Nunan et al., 2003). Accordingly, land-uses with continual inputs of labile carbon, such as grasslands were found to yield more EPS than their arable or fallow counterparts (Redmile-Gordon et al., 2020).

Ecological functions of soil biofilms

Biofilms consist mainly of microbial cells and self-produced EPS. The EPS matrix determines adhesive and cohesive properties of biofilms and enhances the adaptability of soil microorganisms (Or et al., 2007b). Accordingly, the soil biofilm confers unique features and functions. For example, EPS matrix protects microbes against dehydration and antimicrobial agents, anchors extracellular enzymes, captures nutrient and cellular products, and facilitates genetic exchange among populations (Flemming et al., 2016; Tecon and Or, 2017).

Protection against desiccation is one of the best-known properties of a soil biofilm. It is the hydrophilic components in EPS that play a critical role in resisting dehydration (Flemming et al., 2016). EPS secreted by microbes establishes a stable interface between

biological and physical components in soil via interfacial interactions including ligand exchange, hydrogen bonding and electrostatic interactions (Cai et al., 2018). During the reduction of hydraulic conductivity, increased water retention in the EPS matrix results in hydraulic decoupling of the biofilm from drier soil pores. EPS thereby maintains local hydrated areas and protects the biofilm cells. The hydrated matrix also enhances soil moisture content at a macro level and promotes nutrient diffusion under dry conditions (Chenu and Roberson, 1996).

Besides protection from desiccation, biofilm also provides physicochemical barriers against toxic substances. Due to the absorption and diffusion barrier, biofilm exhibits significantly enhanced tolerance to antimicrobial agents. For example, heavy metals can be accumulated in biofilm matrix via biosorption, bioprecipitation, intracellular accumulation and redox immobilization. The anionic charged functional groups, including hydroxyls, carboxyls, amides, amines and phosphorylase, interact with the positively charged metal ions. The microaerobic microenvironment in biofilm also facilitates *in situ* metal bioreduction. Metals such as Pd, Se, Cr, Tc and U were found to be reduced to low valent species and were immobilized in biofilm (Ahmed et al., 2012).

The binding of an EPS matrix with microbial cells in close proximity may establish stable spatial interactions. Soil microorganisms share their habitat with genetically diverse neighbors, leading to competitive or cooperative microbial interactions and determining community diversity and functional traits. The proximity of cells in biofilms facilitates the conjugative transfer of antibiotic resistance genes (ARGs). The EPS matrix provides a feasible environment to increase the stability of plasmids and the host range of mobile genetic elements. The close interaction between biofilm cells also promotes intercellular interaction like quorum sensing to enhance the conjugation of ARGs. Compared with free-living cells in the surrounding environment, the antibiotic-resistant plasmids exhibit a significantly higher conjugation transfer frequency in biofilms (Wu et al., 2021). Moreover, the spatial or physical orientation of biofilms can affect profoundly the way populations share genetic information. Biofilm environments also confer selective effects on plasmid-encoded traits. By evaluating the persistence of plasmids in their receptors and the local competitiveness of the host, biofilms can affect the transconjugants during horizontal gene transfer and further promote the spread of genetic elements via vertical gene transfer (Wu et al., 2021).

Soil biofilms have developed very effective strategies to capture water soluble nutrients, for example, from the substratum. This strategy depends mainly on the passive sorption characteristics of the sponge-like EPS matrix, which influence the exchange of nutrients, gases and other molecules between biofilms and the environment (Or et al., 2007a). Biofilms contain a variety of anionic and cationic binding sites able to bind nutrients at very low concentrations. The trapped and accumulated nutrients can sustain biofilm growth in severely undersupplied environments. In addition to soluble substances, suspended solids like particulate organic matters can be captured by biofilms and incorporated into the matrix (Flemming et al., 2016).

Future prospects

While soil biofilms may be expected to contain a small fraction of the total microbial biomass, they may contribute substantially to soil physical and biogeochemical processes. However, most of our existing knowledge about soil biofilms was obtained through parallel understanding of biofilms in clinical and aquatic systems. There are still fundamental questions and basic technical issues needed to be resolved. These include distinguishing biofilm-cells from free-living sessile or planktonic cells, elucidating the soil biofilm development processes, understanding triggers for biofilm phenotypes, visualizing spatial distributions of different populations within assemblages, and clarifying their functional roles. Simplified model system like artificial soil and synthetic biofilm communities can be initiated to examine the fundamental properties of soil biofilms. Improvements, refinements and combinations of existing techniques and novel approaches are needed to gain a comprehensive understanding of soil biofilm processes (Table 1). For example, non-invasive planar optode imaging can be employed in microcosm systems to resolve the temporal-spatial distribution of microbial activities in soil biofilms. The advent of next-generation physiological analyses presents opportunities to reveal the phenotypes of individual cells in biofilms via non-destructive approaches (Hatzenpichler et al., 2020). These advances will provide a clearer picture of spatial heterogeneity and microbially-mediated biogeochemical processes, and thus help to develop more sustainable soil management practices.

Soil ecosystems exhibit extreme heterogeneity in biological and physicochemical properties. Biogeographical assessments across landscape scales are important to understand the ecological significance of biofilms in soils. The development of omics techniques enables the survey of soil microbial features at multiple scales, which outlines the microbial diversity, spatial organization and functionality. However, due to the intrinsic complexity and the limited understanding of soil biofilm processes, there is a lack of specific molecular, taxonomic and functional signatures for biofilms. Therefore, it remains challenging to implement currently available omics techniques to quantify and characterize soil biofilm community.

Microfluidics, a widely applied approach in environmental microbiology, is a promising technique for biofilm research. Soil microfluidic chips provide optical access to natural opaque soil systems and enable direct characterization of microbial growth and communal interactions in microstructure or chemically controlled environments. However, *in situ* analysis of complex interactions with the high spatial and temporal resolution is still lacking. Microfluidic devices, combined with appropriate fluorescent tagging and imaging techniques, can detect chemical changes in the microbial biofilm matrix and metabolic activities like cell growth, movement and nutrient usage (Pucetaite et al., 2021). The application of advanced micro-spectral techniques in microfluidic soil chips, namely infrared absorption, Raman scattering and X-ray micro-spectral techniques based on synchrotron radiation are also

Table 1 Overview of techniques for soil biofilm research.

Techniques	Measured Parameters	Advantages	Disadvantages
Synthetic biofilm community	–	Precise control of community composition	Limited resemblance to natural ecosystem
Planar optode	Temporal-spatial distribution of microbial activities in soil biofilms	Non-invasive, real-time, and high resolution	Multi-analyte sensing unavailable
Meta-omics	Microbial diversity, spatial organization and functionality	Characterize biofilm complexity and variability at multiple scales; high-throughput; culture-independent	Each platform has different technological limitations due to sample preparation, sequencing platforms and depth, limits in instrumentation, and dynamic range.
Next-generation physiology approaches	Examine the physiological responses of biofilm communities	Characterization of uncultured microorganisms with unprecedented speed; high spatial resolution; non-destructive analysis	Mechanisms not well understood
Soil microfluidic chips	Enable direct characterization of microbial growth and communal interactions in well-defined microstructure	Precise control of physicochemical properties at micrometer scale and simulate specific growth conditions	Simulation still highly unnatural
Advanced microspectral techniques coupled with microfluidic chips	Physicochemical and biological reactions within biofilms with high spatial and temporal resolution	High reproducibility; in situ measurement at micro-scale resolution; simplified sample preparation	

making further breakthroughs at the frontier of soil science (Pucetaite et al., 2021). These chemical analyses can reveal physicochemical and biological reactions within soil system with the high spatial and temporal resolution. In future, microfluidic devices should be designed to represent and simulate unique changes in the soil environment, for example the drying and wetting with the natural occurrence of water infiltration and evaporation events. It is expected that microfluidic devices operating in controllable unsaturated soil conditions will deepen our understanding of soil biofilms and provide new perspectives for understanding soil microbial ecological processes (Cai et al., 2019).

Evidence-based soil management holds the key to improvements in the sustainability of agriculture and horticulture. Researchers seek to establish a quantitative framework to track individual cells and communities in a virtual soil environment, and to provide guidance for using experimental and monitoring activities. This includes incorporating soil dynamic processes into mechanical models and refining the models with new insights from more controlled observations. In future, the basic characteristics of soil biofilms should be assessed by studying increasingly complex synthetic model communities in the laboratory (Tecon and Or, 2017).

Conclusion

Soil biofilms are aggregates of microbial cells embedded in a self-produced EPS matrix. The EPS matrix binds cells in a biofilm and creates a unique environment for biofilm-dwelling cells that exhibit emergent properties absent in free-living cells. Soil biofilm formation has been shown to enhance microbial survival, community diversities and metabolic activities. The combined future study of natural and artificial biofilm communities can help reveal the mechanistic geochemical interactions driving key soil and biofilm processes. These advances in research will help us to obtain a more comprehensive, accurate and in-depth understanding of both soil and the microbiome.

Abstract

Biocrusts are a thin, distinct, cohesive layer at the surface of terrestrial soils, engineered by microbes and cryptogams. They are found throughout the world, especially in drylands, but are also known from cold-limited environments and some disturbed mesic temperate environments. Biocrusts are multifunctional. They are photosynthetic, reduce erosion, accumulate nutrients, influence water redistribution and storage, and interact with other biotic communities. Biocrusts are sensitive to both climate change and physical disturbances, and can be lost much faster than they can subsequently recover. Assisted biocrust recovery techniques are being developed as biocrusts are increasingly incorporated into land management decisions.

Glossary

Bryophyte True land plants that lack vascular tissue and do not reproduce from seeds. There are three groups of bryophytes: mosses, liverworts and hornworts.

Cryptogam A “plant” (sensu Linnaeus) that does not flower or reproduce from seeds. This is a historical collective term for related and unrelated organisms including algae, lichens, mosses, ferns, fungi, and cyanobacteria.

Cyanobacteria A phylum of photosynthetic bacteria. They are also commonly referred to as blue-green algae, though they are no longer classified as algae because they are prokaryotes.

Desiccation tolerance The ability of an organism to lose a large proportion of its body water, but remain alive in an inactive, dry state. Desiccation tolerance also involves the ability to rehydrate and reactivate metabolic processes after a dry, inactive period.

Lichen A symbiotic partnership between at least two organisms, always including a fungus that houses either a cyanobacterial or algal partner within it. Some lichens have fungal, cyanobacterial and algal components, while others may have more than one fungal species involved.

Poikilohydry Lack of ability of an organism to regulate water uptake or loss, leading to equilibration of cell or tissue water content with the environment. Poikilohydric organisms that occupy dry environments are often desiccation tolerant.

Key points

- Biocrusts are a distinct, thin cohesive and photosynthetic layer at the soil surface held together by biota
- Biocrusts are found throughout the world in drylands, cold-limited environments and disturbed mesic ecosystems
- Biocrust biota include photosynthesizing organisms, such as cyanobacteria, lichens, algae, mosses and liverworts, and heterotrophs, such as fungi, other bacteria, and microfauna
- Biocrusts can tolerate drying without dying, reduce erosion, accumulate nutrients, influence water redistribution and storage, and interact with other biotic communities
- Biocrusts may be lost or degraded by physical disturbances and climate change, but increasingly are being considered in ecological restoration and land management

Introduction

Biological soil crusts, increasingly referred to in the shorthand as “biocrusts”, may have originated on land long before the colonization and radiation of vascular plants. Multiple lines of evidence suggest the existence of terrestrial communities extending billions of years into Earth’s past. Cyanobacteria are one group of organisms that possessed many of the traits that would have enabled life on land - oxygenic photosynthesis, ultraviolet tolerance mechanisms, desiccation tolerance, nitrogen fixation (in some taxa) - and possibly occupied land ~2400 million years ago. Because cyanobacteria are photo-autotrophic, they may have formed biocrusts or biocrust-like communities on soil surfaces (Weber et al., 2016).

Eukaryotic algae are much younger, but still older than and ancestral to all land plants. They may have existed on terrestrial surfaces ~500 million years ago or earlier. Bryophytes, including mosses and liverworts, and lichens are younger still, and originated on land between ~400–500 million years ago, either evolving from green algal ancestors in the case of bryophytes or arising from fungal symbioses with cyanobacteria or algae in the case of lichens. Therefore, it is highly plausible that complex biocrust communities consisting of any combination of cyanobacteria, green algae, mosses, liverworts or lichens, and associated microbes, predated the fossil record of all tracheophytes (vascular plants), and very likely preceded the phanerogams (seed plants) that eventually came to dominate the land surface (Weber et al., 2016). Biocrusts are still extant, widespread and sometimes abundant today in many different ecosystems, serving as modern analogs of early terrestrial communities.

Recognition of biocrusts as a distinctive community type, and interest in their ecological roles came about relatively recently, mostly after the mid- twentieth century. Ecological studies of biocrusts became more common in the 1980s and 1990s, and have proliferated at an increasingly fast rate, subsequently becoming a major subject of ecological research (Weber et al., 2016). Multiple synonyms have been used to refer to these communities with replacements over time. Among others, these included cryptogamic, microbiotic, microfloral, microphytic, and cryptobiotic crusts; these were either inconsistently used, or fell out of favor, for example because they were not considered to be inclusive of all the biota that generate biocrusts. Most authors are currently using the terms biological soil crusts or biocrusts (Belnap and Lange, 2003, Weber et al., 2016). Increasingly, biocrusts are being compared to a “living skin” on the soil surface (Bowker et al., 2018).

A recent synthesis proposed a universal definition for biocrusts, encompassing the wide variety of communities referred to as such in the ever-expanding literature.

Biological soil crusts (biocrusts) result from an intimate association between soil particles and differing proportions of photoautotrophic (e.g., cyanobacteria, algae, lichens, bryophytes) and heterotrophic (e.g., bacteria, fungi, archaea) organisms, which live within, or immediately on top of, the uppermost millimeters of soil. Soil particles are aggregated through the presence and activity of these often extremotolerant biota that desiccate regularly, and the resultant living crust covers the surface of the ground as a coherent layer.

(Weber et al., 2022)

This definition brings together 4 major intersecting elements: habitat, physical structure, functional characteristics, and taxonomic composition (Weber et al., 2022). Biocrusts inhabit terrestrial soils in habitats in which the soil surface dries regularly. Biocrusts form a thin - usually millimeters thick, or a few centimeters at most - distinctly structured layer at the soil surface that differs from underlying soil. This structure arises specifically because of the functional attributes of biocrusts: (a) biocrusts always contain photosynthetic organisms that must occur at the soil surface where light is available, (b) biocrust organisms aggregate soil, generating the characteristic physical structure, and (c) because of their soil surface habitat, they are tolerant of extreme biological conditions such as desiccation. Biocrusts are dominated by certain lineages of photoautotrophs belonging to the historical grouping of “cryptogams” and exclude tracheophytes. Though this grouping of taxa is not phylogenetically supported, it does express commonality in several functional traits (small size, poikilohydric common habitat preferences, etc.). Several examples of communities that fall within this definition are illustrated in Fig. 1.

Fig. 1 Varied forms, compositions, colors and textures of biocrusts. (A) A series of distinct biocrust communities in close proximity differing in relative abundance of cyanobacteria, mosses and lichens, diversity, and spatial heterogeneity; only the upper right panel depicts a surface lacking biocrust (New South Wales, Australia). (B) A cyanobacteria-dominated biocrust with dark patches indicative of microbial sunscreens (Utah, USA). (C) A species-rich biocrust featuring multiple variously colored lichens, interspersed with mosses and patches of cyanobacterial biocrust (Idaho, USA). (D) A microtopographically-complex biocrust, dominated by cyanobacteria; inset highlights elongated micro-ridges and valleys (Utah, USA). (E) A well-developed biocrust composed of lichens, liverworts and mosses growing in a disturbed mesic area, approximately 20 years after ecological restoration activities (Iceland).

Global distribution

Biocrusts are a global community type, found on all continents in many different habitats (Weber et al., 2016). One of the most common shared attributes among biocrust habitats is an open vegetation canopy that allows substantial light to reach the soil surface. This is because biocrusts are photosynthetic, but extremely limited in height, and therefore cannot compete for light with most vascular plants. Biocrusts inhabit only terrestrial habitats, not aquatic or marine ones, and are not typically found in habitats flooded with water for extended periods of time.

Biocrusts are perhaps best documented in the drylands of the world, regions with a high ratio of potential evapotranspiration to precipitation, where water limits vascular plant distribution (Fig. 2). This includes a broad range from subhumid grasslands and savannas and some open forests, semi-arid shrublands, steppes, grasslands, savannas, desert shrublands and grasslands, and some hyper-arid regions. Notable ecoregions supporting well-documented biocrusts include the Negev Desert of Israel, the Kalahari Desert and Sahel region of Africa, the Colorado Plateau and other deserts of North America, semi-arid alpha grass steppes of Spain, Eucalypt woodlands and drier deserts of Australia, northern cool and cold deserts of China (Gurbantunggut, Tennger, Mu Us deserts and the Loess Plateau), among many others (Weber et al., 2016, 2022). In these environments, biocrusts may occupy and sometimes fill the interspaces in between vascular plants, and may also be found underneath the canopy of vascular plants.

Given the wide variety of potential dryland habitat types, dryland biocrusts have been documented and studied on all continents (Rodríguez-Caballero et al., 2018; Fig. 2). In a recent study focusing on biocrusts documented in warm and cool deserts (excluding cold deserts), it was estimated that about 24% of the terrestrial land surface was suitable for dryland biocrusts and that about 12% of the terrestrial surface is currently occupied by biocrusts (Rodríguez-Caballero et al., 2018; Fig. 2).

Fig. 2 The global distribution of biocrust studies in both dryland and non-dryland environments (map: Emilio Rodríguez-Caballero). The niche and coverage of biocrusts (modeled in Rodríguez-Caballero et al., 2018; training data included biocrust occurrences in hot and cool drylands but excluded polar regions and anthropogenic landscapes) is shown alongside dryland regions according to UNCCD (UNEP-WCMC, 2007).

Biocrusts are also documented to occur in cold-limited environments such as alpine and high latitude regions, including Antarctica (Jung et al., 2018). Some notable examples include Devon Island and the Canadian Arctic, Svalbard, Greenland, highlands of Iceland, the Austrian Alps, and the Antarctic dry valleys and maritime regions (Weber et al., 2022). Biocrusts of these high altitude or latitude cold regions are not as widely documented or studied as in the drylands, thus their full distribution is not known. In these regions, water and cold temperatures may be co-limiting, either because of little precipitation or because water is often in a frozen state (Weber et al., 2022).

The final climatic zone where biocrusts may occur is in disturbed, mesic regions or in unique soil environments within mesic regions (Corbin and Thiet, 2020). Because climatically-induced stress is less in this type of environment than other typical biocrust environments, the disturbance provides a window of opportunity for biocrust development before a complete coverage of vascular plants can reestablish. Biocrusts are found in primary successional environments, for example colonizing land exposed by glacial retreat (Weber et al., 2022) and in secondary successional settings, such as following stand-destroying wildfires in forested regions throughout the world, where fast-growing moss biocrusts may form (Weber et al., 2022). Biocrusts have occasionally been documented in agricultural soils, either after abandonment, or between tillage events. In some cases, stressful or unusual soil conditions might limit vascular plant canopy closure, and combined with occasional disturbance, create a long-term niche for biocrusts, for example in pine barrens of North America or mesic inland dunes of Germany (Weber et al., 2022). The occurrence of biocrusts in the wide array of situations, described above, expands the probable map of biocrust occurrence, even if only temporarily, to most terrestrial ecoregions.

The factors controlling biocrust occurrence, degree of development and composition are best understood in the drylands and differ strongly with the spatial scale (Weber et al., 2016). Biogeographical patterns emerge, for example, geographical distance or time of land mass isolation, mostly at global and continental scales, that influence biocrust species composition and structure. Climatic (and micro-climatic) factors are a ubiquitous influence at all scales from global to micro-scale. Chief among the climatic factors are the interactive effects of temperature and precipitation regimes, which co-determine the amount, mode and timing of soil moisture availability at the soil surface. Soil surface moisture availability for biocrusts is best understood not as an amount of water, but rather the residence time of a sufficient amount of water to activate biocrust metabolism. Extremely low moisture availability, such as in hyper-arid regions, tends to limit both the total amount of biocrust present and restrict biocrust composition to only the most stress-tolerant species. Additional moisture availability, e.g., arid to semi-arid regions, promotes greater biocrust cover and a wider variety of possible compositions (including lichen- or moss-dominated types).

Composition and global biodiversity

Biocrusts are dominated by photoautotrophic organisms (those with the ability to photosynthesize and fix their own carbon) including cyanobacteria, eukaryotic algae (multiple lineages), mosses, liverworts and lichens (Weber et al., 2022). Cyanobacteria are among the most ancient and widespread members of the biocrust community, and are often dominant or co-dominant in drylands and elsewhere. There are three different functional types of cyanobacteria: 1) filamentous biocrust builders, which create long sheathed colonies which bind soil particles together and create stability, 2) biocrust residents which add additional functionality such as N-fixation, and 3) cyanobacteria that arrive via stochastic processes and do not permanently reside in biocrusts (Weber et al., 2016). Eukaryotic Algae, such as chlorophytes and diatoms, are another ancient component of biocrusts, widely dispersed, co-dominant or dominant in some environments but often found in low abundance in drylands (Weber et al., 2016). Lichens are prominent symbiotic components of biocrusts, both functionally and visually, and are mostly macroscopic. They harbor an impressive amount of diversity in morphologies and functional traits that determine ecosystem process rates (Mallen-Cooper and Eldridge, 2016). Bryophytes, a collective term for mosses, liverworts, and hornworts, are conspicuous, macroscopic, widespread and sometimes dominant in biocrusts. Similar to lichens, the functional trait diversity of bryophytes allows for a large diversity of influential traits within the biocrust community (Mallen-Cooper and Eldridge, 2016). Both lichens and bryophytes tend to be less common where soil moisture is extremely limiting (e.g., hyperarid regions), but attain a higher degree of dominance as effective precipitation increases (e.g. semiarid regions; Weber et al., 2016).

Biocrusts are also inhabited by heterotrophs, some of which may also play roles in biocrust formation alongside the photoautotrophic components (Weber et al., 2022). These include fungi, bacteria (other than cyanobacteria), and microfauna, including protozoa, nematodes, tardigrades, rotifers, and microarthropods. Fungi (excluding lichen-forming types) are important biocrust components, but are poorly studied in comparison to lichenized fungi because of their microscopic nature and because the majority are not readily culturable. Ascomycetes are particularly well-represented in biocrusts. Because of their filamentous hyphae, many fungi likely contribute to biocrust building, though that role is understudied. Fungi may also mediate nutrient exchanges between biocrusts and vascular plants. Some fungi live on or within other biocrust biota as commensals, parasites or pathogens (Weber et al., 2016). Bacteria (phyla other than Cyanobacteria) comprise a large proportion of the microbial community members in biocrusts. Bacterial diversity estimates and compositions in biocrusts (and in general) are highly dependent on the methodology employed. Only in the past three decades have researchers been able to advance from culture-dependent methods to early culture-independent molecular methods to next-generation high-throughput sequencing approaches, capturing an increasingly complete picture of bacterial communities (Weber et al., 2016). Bacterial communities can be highly diverse; it is not unusual for several phyla to be detected in biocrusts containing a large number of operational taxonomic units (OTU) or amplicon sequencing variants (ASV) using modern methodologies. Actinobacteria, Proteobacteria, Bacteroidetes and Acidobacteria are often among the most abundant phyla (Weber et al., 2016). Protozoa, nematodes, tardigrades, rotifers and microarthropods are the major groups of animals and animal-like protists that complete a complex food web within biocrusts (Weber et al., 2016).

Worldwide, at least 68 liverworts, 255 mosses, 553 lichens, 320 species of cyanobacteria and 353 species of eukaryotic algae have been reported to inhabit biocrusts (Weber et al., 2016; updated in Bowker et al., 2017). These are pooled estimates from papers which include species lists and are not expected to be a complete accounting of the global species pool of inhabitants for the following reasons:

1. The available literature has multiple geographic gaps.
2. In some of these groups, cyanobacteria in particular, taxonomy is in flux and increasingly reliant on molecular approaches to resolve taxa that are morphologically very similar (e.g. *Microcoleus vaginatus* and the *Microcoleus steenstrupii* complex); similar appearance hides multiple species and even families (Fernandes et al., 2021).
3. The estimates above exclude important groups of heterotrophic biocrust biota. No attempts have been made to estimate the global diversity of bacterial or fungal diversity at OTU or ASV levels within biocrusts, and most studies of biocrust microfauna are not conducted at the species-level.

Therefore, the global species pool is likely much larger than the 1549 species identified to date.

There are several multi-continental or even global taxa that are commonly reported from biocrusts and which may be among the dominant species (Bowker et al., 2017). In fact, some geographically distant biocrust floras have substantial overlap. Nonetheless, there is considerable variation among biocrust communities from place to place, regulated by differing forces at different scales of observation. At the largest scales, dispersal limits may create differentiation between biocrust floras of different regions. Climatic and edaphic factors also influence compositions at large to small scales because these are two major elements of species' ecological niches.

Because biocrusts vary in their composition from place to place, a few classification schemes have been used which facilitate comparisons among regions. Most commonly, biocrust communities are classified by their dominant photoautotrophic component, e.g., moss, lichen or cyanobacterial biocrusts, among other possibilities (e.g., Havrilla et al., 2019). Cyanobacterial biocrusts are sometimes further divided into "light" and "dark" types, based on their pigmentation, which is reflective of the relative abundance of certain genera. Ordinal scales of development have been proposed, which simultaneously capture darkness, succession, community compositional shifts, and differences in function in the whole biocrust community (Belnap et al., 2008). The physical structure and morphology of biocrusts has also been used to differentiate different biocrust types. For example, flat, rugose, pinnated, and rolling morphologies are linked to different habitat types and are expected to have different functional

properties in ecosystems (Weber et al., 2022). Functional-morphological groups have been proposed for some taxonomic groups of biocrust organisms to reduce the need for taxonomic expertise in biocrust studies; these groupings effectively encapsulate multiple functional traits (Mallen-Cooper and Eldridge, 2016).

Functional properties and roles in ecosystems

Desiccation tolerance

Biocrusts lack roots, do not have vascular tissue for water transport (with the exception of a handful of moss taxa), and do not have stomata to regulate water loss. Rather, water is absorbed directly from the environment (e.g., rainfall, fog droplets, wet surfaces) and is subsequently lost by evaporation, leaving biocrust organisms in a desiccated state. Biocrust organisms dry without dying. They can suspend metabolic processes, then resume them upon rehydration, often within seconds (Fig. 3A). Therefore, they are considered desiccation tolerant, and many biocrust organisms can survive months or longer in the dry state.

There are limits to this ability, however. Desiccating biocrust organisms endure cellular damage, e.g., to their membranes, or oxidative stress, thus repair is often an early priority upon reactivating metabolic processes. Because of the cost of repair, respiration rates are often higher than photosynthetic rates early in a rehydration event (Weber et al., 2016). If the hydration event is too short to attain a positive carbon balance, the organism will experience a net loss of carbon during the event. A series of such events can be lethal (Weber et al., 2016).

Tolerance to other stresses

Ultraviolet radiation

Because of their position on the surface of the soil, and the open-canopied nature of their habitats, biocrusts are exposed to the full light spectrum, including ultraviolet radiation (UV-A and UV-B). Many biocrust organisms have at least one strategy or mechanism to cope with this stressor, some apparently ancient. Bundled, motile, filamentous cyanobacteria have an avoidance strategy. These

Fig. 3 Biocrust functional properties and roles in ecosystem functions. (A) Biocrust organisms, such as the moss *Syntrichia ruralis*, are poikilohydric and desiccation tolerant. The significance of this is that they can dry without dying, entering an inactive state, and resume activity upon rehydration (photo: Theresa Clark; Arizona, USA). (B) A greenhouse-grown biocrust generates aggregation of the soil surface through a proliferation of cyanobacterial filaments that weave a cohesive surface layer (photo: Kristina Young; Arizona, USA). (C) Stark differences in surface pigmentation due to experimental repeated trampling of biocrusts, increasing albedo (photo: Sasha Reed; Utah, USA). (D) Low-growing vascular plants cluster within and directly adjacent to gray patches of liverwort-dominated biocrust (highlands of Iceland).

species may glide within a polysaccharide sheath onto the surface of the soil, or downward under the protection of soil particles and other organisms (Belnap and Lange, 2003). Non-motile organisms, e.g., surface-bound cyanobacteria, lichens, and bryophytes cannot pursue this avoidance strategy, but have a variety of pigments that assist with either reducing damage caused by UV exposure or mitigating it (Belnap and Lange, 2003). For example, cyanobacteria and cyanolichens may have sunscreen pigments, like scytonemin or mycosporine-like amino acids which absorb UV radiation, intercepting it before it can damage living cells and tissues (Belnap and Lange, 2003). Some families of pigments, carotenoids and xanthophylls found in all major groups of photosynthetic biocrust organisms, are anti-oxidants capable of quenching free radicals and reducing oxidative stress caused by UV exposure (Belnap and Lange, 2003; Weber et al., 2016).

Temperature

Many biocrust organisms appear tolerant of temperature extremes because they inhabit some of the hottest and coldest habitats on Earth. However, this assessment is deceptive because often the most extreme temperatures occur when biocrusts are desiccated and inactive (Weber et al., 2016). The periods of time in which biocrusts are actually hydrated and active often occur in the portions of the year with milder climates (for example in the coolest season of warm climates). When hydrated, many biocrust organisms (e.g., mosses, most lichens) may have relatively cool temperature optima. Temperatures above 30 °C are often suboptimal if not stressful for many species, and some taxa have the ability to remain active at temperatures close to 0 °C (Belnap and Lange, 2003).

Ecosystem functional roles

Soil surface stability

Biocrusts are important in soil surface stabilization and dust trapping. Filamentous structures of biocrust biota weave through the top few millimeters of soil, binding loose soil particles together and generating a distinguishable, thin aggregated layer on the original soil surface (Belnap and Lange, 2003; Fig. 3B). These structures include filaments (trichomes) of cyanobacteria, rhizoids of mosses, rhizines of lichens, and hyphae of fungi. Biocrusts also stabilize soil surfaces through the exudation of *exo*-polymeric substances, notably polysaccharides, which can act as glues or provide charged surfaces for adsorption. Some of the major cyanobacteria create a matrix of polysaccharide sheaths in which their colonies also live. Biocrusts may also improve soil surface stabilization through the accumulation of organic matter and fine soil particles. Soil surfaces aggregated by biocrusts are much more resistant to both water and wind erosion than soils that lack them. Notably, researchers estimated that global dust flux - an outcome of wind erosion - would be 60% greater in the absence of soil stabilization by biocrusts (Rodríguez-Caballero et al., 2022). Biocrusts not only reduce dust emissions at the source but also trap and accumulate dust particles originating from other areas.

Carbon fixation

Biocrusts are net photosynthetic communities. Although the photosynthetic machinery is the same as in vascular plants, biocrust photosynthesizers are active only when hydrated, which may be only a small proportion of the year in some biocrust habitats. Because of this, the overall amount of carbon fixed on a per area basis will be much smaller than that achieved by vascular plants (even after taking size into account; Weber et al., 2016). Both chlorophyll content and maximal photosynthetic rate varies widely, even within functional groups (Weber et al., 2016). Maximal photosynthetic rates of biocrust organisms differ as a function of the dominant phototroph. Under optimal conditions it can be comparable to or exceed that of conifer needles, such as in lichens, but may be much smaller in cyanobacterial biocrusts (Belnap and Lange, 2003). In general, biocrust organisms with less dry mass per area have a greater maximum net photosynthetic rate (Weber et al., 2016). Several biocrust species have been characterized as “sun plants” in the laboratory (Belnap and Lange, 2003), but in the field the same species may be more successful in less exposed habitats because period of hydration there may be longer. Measuring net carbon uptake of biocrusts *in situ* is challenging because biocrust C uptake may be smaller than respiration from the underlying soil column which might contain vascular plant roots. Long-term studies of biocrust-covered soils tend to show net respiration for much of the year, punctuated by periods of net photosynthesis when the climate is optimal for biocrust photosynthesis and growth (Weber et al., 2016). Partitioning the gas exchange activity of natural biocrusts from activity below the biocrusts in the field over the long-term may require technological advances (Weber et al., 2016).

Nitrogen fixation and nutrient cycling

Biocrusts harbor species with the capability of fixing atmospheric di-nitrogen gas and converting it to ammonium, a key form of mineral nitrogen, which is an essential nutrient for plants and microbes. This is a crucial process because most terrestrial ecosystems are limited by the availability of mineral nitrogen. Some biocrust cyanobacteria, and some biocrust lichens with cyanobacterial photobionts have this ability, along with some heterotrophic bacteria that reside in biocrusts. Annual nitrogen fixation by biocrusts varies by orders of magnitude from study to study as the biocrust communities and methodologies change (Weber et al., 2016). Elbert et al. (2012) estimated a global average rate of 6 kg N ha⁻¹ y⁻¹, based on published values in the literature. In that same study, a total of 25.7 Tg y⁻¹ was estimated to be fixed by cryptogamic ground covers (mostly various types of biocrusts) in desert and steppe environments, which corresponds to about a quarter of the nitrogen fixation on land. Rodríguez-Caballero et al. (2018) arrived at a very similar estimate of global nitrogen fixation attributable to dryland biocrusts. In addition to fixing nitrogen, biocrusts harbor organisms that contribute to mineralization and other transformations of carbon, nitrogen, phosphorus and other nutrients (Delgado-Baquerizo et al., 2018; Weber et al., 2016).

Hydrological functions

Biocrusts have a pervasive influence on most soil processes pertaining to water (Eldridge et al., 2020). In some regions biocrusts slow infiltration and promote runoff, while in others they are reported to do the opposite (Weber et al., 2016). Biocrusts often retain more moisture than soils lacking biocrusts, but may concentrate it near-surface (Eldridge et al., 2020). Biocrusts may increase or impede evaporation rates. Biocrusts increase the capture of fog, dew and vapor, but the magnitude of this effect varies widely by ecosystem (Li et al., 2021). This wide array of influences comes about because biocrusts change many soil properties that affect water retention and transport such as temperature, texture, surface roughness, aggregation, pore size distribution and connectivity to the surface, and organic matter content (Belnap and Lange, 2003). In some patterned ecosystems, biocrusts are part of a system in which water is transported from runoff zones to run-on zones, boosting overall productivity of the ecosystem (Belnap and Lange, 2003).

Soil surface albedo and heat storage

Albedo refers to the proportion of solar radiation reflected from a surface, such as a soil. Albedo would generally be expected to be negatively related to the amount of heat absorbed and stored by surface soils. Biocrusts modify many soil surface properties such as darkness, roughness and moisture content, all expected to reduce albedo. Many, but not all, biocrusts darken as they develop and mature due to increasing prevalence of highly pigmented species, and disturbances and other stressors may reverse development and decrease darkness (Fig. 3C). Shifts in community composition induced by experimental climate change treatments, increased soil surface albedo by 30% through loss of darker taxa and replacement with lighter taxa (Rutherford et al., 2017). Other authors have focused on the effect of biocrust darkness and development on temperature. Mature cyanobacterial biocrusts can warm soil surfaces by as much as 10 °C, and the degree of warming can be very well predicted by the concentration of a single sunscreen pigment (Couradeau et al., 2016). Albedo and soil surface temperature do not always change in lockstep, however. Xiao and Bowker (2020) found that moss-dominated biocrusts consistently lower albedo year-round, especially when dry, but were only warmer than bare soils under dry conditions and were cooler under wet conditions.

Interactions with other biota

Because biocrusts modify many properties of the soil habitat, they also shape the structure and composition of other assemblages of biota. Biocrust influences on vascular plants are the most widely documented examples but are also extremely variable and contingent on the life history stage and traits of the vascular plants, in addition to the type of biocrust (Havrilla et al., 2019). Biocrusts may promote (Fig. 3D), inhibit or have neutral effects on a given plant species, and these effects may shift across plant ontogeny (e.g., germination vs. subsequent growth). These effects may be attributable to a wide variety of mechanisms including, but not limited to, prevention of radical penetration into soil, or concentration or redistribution of key soil resources such as water and nutrients. Rare studies of biocrust effects on entire plant communities have found that biocrust properties such as total cover, richness or relative moss dominance can influence key properties of plant communities such as native plant dominance over exotic plants (Bowker et al., 2022).

Though less widely studied, biocrusts also modify the habitat properties for soil bacteria and fungi, in addition to supplying potential food resources for these groups. As an example, in a study on three continents, the presence of biocrust mosses constrained the variability of microbial communities attributable to aridity, suggesting that the mosses buffer the microclimate experienced by soil microbes (Delgado-Baquerizo et al., 2018). Biocrust influences may be detectable more broadly in soil food webs, for example more successional developed biocrusts tend to support greater abundance and diversity of soil microfauna (Weber et al., 2016).

Multifunctionality

Ecologists are increasingly focusing on multifunctionality of ecosystems, or the ability of the ecosystem to carry out multiple functions simultaneously, as opposed to focusing on single ecosystem functions like productivity. Biocrusts are multifunctional, because they simultaneously contribute to many of the functions listed above and others. For example, working with samples from three continents, Delgado-Baquerizo et al. (2016) compared indicators of carbon, nitrogen and phosphorus cycling in biocrust patches compared to adjacent patches lacking biocrusts. All indicators were integrated into two types of multifunctionality index and the authors found that biocrusts enhanced multifunctionality in semi-arid and, especially arid environments, but not dry-subhumid or humid environments. The degree of multifunctionality of biocrusts has been linked to properties of the biocrust community, for example species richness, evenness or community composition (Bowker et al., 2017). Recent work suggests that global change factors, such as nitrogen deposition or drought, may strengthen the influence of biocrusts on multifunctionality (Dias et al., 2020; Su et al., 2021).

Threats and Recovery

Biocrusts are sensitive to both climate change and physical disturbances. Many of the ecosystems where biocrusts thrive are among the most threatened and disturbed as a result of human activities (Právělie, 2016). In addition, it is predicted that biocrust coverage will decrease substantially with land use and climate change activities within the 21st century (Rodríguez-Caballero et al., 2018).

Understanding the ways in which biocrusts are damaged and their subsequent recovery trajectories, natural or assisted, is necessary to predict ecosystem health for drylands and other ecosystems where biocrusts are common. Below we describe the effects of physical disturbance and climate change on biocrusts, and then discuss natural and assisted recovery for biocrusts in response to physical or climate disturbance.

Physical disturbance

In ecosystems in which abiotic stress is high, such as drylands, disturbances that break or compress the soil surface are detrimental to biocrusts and tend to have similar outcomes across ecosystems (Weber et al., 2016). These disturbances include land clearing and tillage, grazing (hoof action), military training (heavy vehicle traffic) and mining (surface soil removal). Of these, grazing is the most extensive land use in the world and is especially prevalent in drylands (FAO, 2020). Damage to biocrusts due to grazing is primarily an outcome of trampling, rather than consumption. The degree of damage sustained may vary among taxa with differing morphologies. The degree of damage sustained is also influenced by elements of the grazing regime, such as intensity or season; higher stocking rates tends to result in greater impacts on biocrusts, as does grazing during dry, warm seasons. Fire can also exert a detrimental effect on biocrusts, through combustion or exposure to heat. The degree of fire damage to biocrusts depends strongly on the fire intensity and patchiness, which is influenced by the amount, connectivity and type of fuel. Response of biocrusts to these varied disturbances are surprisingly similar in many cases (Weber et al., 2016). The most commonly reported changes include decreases in biocrust total abundance, and a simplified community structure consisting mostly of early successional community members such as cyanobacteria and a loss of later successional mosses and lichens (Ferrenberg et al., 2015).

The effect of the scale of disturbances is an understudied aspect of their impacts upon biocrusts. Small disturbances are likely to have limited effects because local propagule sources remain, allowing biocrusts from surrounding areas to colonize the disturbed area, assuming conditions are adequate for recovery. Large-scale disturbances could lead to a much slower recovery time because soil erosion could be initiated, leading to loss of soil fertility and other resources, alongside degradation of the vascular plant community. Recovery in these scenarios, compounded by a lack of local propagule sources, would hypothetically be much slower and may require active rehabilitation (Bowker, 2007).

In less stressful ecosystems (e.g., mesic regions), biocrusts may have a very different relationship to disturbance. Normally, these ecosystems would not provide much niche space for biocrusts owing to high vascular plant productivity and canopy closure. Disturbances can create an opportunity, at least temporarily, for biocrust establishment by creating open space in which sunlight penetrates to the exposed soil surface (Bowker, 2007). For example, biocrusts composed primarily of mosses or liverworts may proliferate after a forest fire. In most such cases, the biocrusts are a type of pioneer vegetation that will eventually be replaced by vascular plant cover, but can help to prevent soil, nutrient and water loss until vascular plants can recolonize (Bowker, 2007). In some cases, unusual soil conditions, such as excessive drainage or extreme shallowness, can interact with disturbance to allow for a more permanent presence of biocrusts in mesic ecosystems (Corbin and Thiet, 2020).

Climate change

Although biocrusts are adapted to life in harsh terrestrial environments, they can be stressed by environmental conditions experienced when active. Thus, if precipitation and temperature regimes shift, biocrusts may be vulnerable to climate change. Most regions on Earth are currently experiencing warming trends. Though precipitation trends are more varied, warming alone is often hypothesized to make dryland environments drier through enhanced evapotranspiration. Thus, a general expectation for dryland biocrusts might be that warmer temperatures or reduced rainfall would reduce the time when the surface soil is hydrated, thereby decreasing opportunities for biocrusts to grow. Experiments have employed various methods to induce warming such as the field installation of passive open-topped warming chambers with infrared heat lamps (Weber et al., 2016). Likewise, researchers have experimentally installed rain-reduction shelters to intercept a portion of the rainfall and induce drier conditions or have altered the pattern of precipitation (Weber et al., 2016). Elevational transplantation has been used to induce warmer and drier conditions simultaneously. To date, experimental studies investigating biocrust susceptibility to climate change suggest that: (1) Warming reduces the prevalence of at least some biocrust components, often lichens or mosses, (2) Effects of rainfall amount are more subtle, but altered rainfall frequency can induce the rapid mortality of mosses (Weber et al., 2016). For example, an experiment increasing temperature and modulating precipitation to come in small pulses led to mature biocrusts losing moss and lichen components, and resetting to an early successional filamentous cyanobacterial community (Ferrenberg et al., 2015). These experimental findings were supported in a long-term observational field study in which nitrogen-fixing biocrust lichens declined sharply in response to high temperatures during a severe drought and did not recover again over the next two decades; this study appears to capture detrimental climate change effects on biocrusts occurring in real time without experimental manipulation (Finger-Higgins et al., 2022). How extensive and impactful might effects of climate change be on biocrusts? A global modeling study projected that due to the synergistic effects of climate change and expected land use change, the global land area suitable for biocrusts may decline by 16–33% by 2070, while actual biocrust coverage might decline by 27–39% (Rodríguez-Caballero et al., 2018). These biocrust losses are estimated to impact global net primary production only a small amount, but could reduce global N-fixation on land by 6–9% (Rodríguez-Caballero et al., 2018), and increase global dust emission by 5–15% (Rodríguez-Caballero et al., 2022). Potential impacts to other biocrust-mediated ecosystem functions have not yet been estimated at the global scale.

Natural recovery from disturbance

Biocrusts can recover from disturbance, but time required for recovery has been estimated at anywhere between a few years to a few millennia (Weber et al., 2016). Biocrust recovery is fastest in climates with greater effective precipitation and greater inherent stability of soils and when disturbances are less severe. Most of the very slow recovery rate estimates of centuries to millennia are associated with arid or hyper-arid conditions, extreme disturbance types, such as tank training or complete removal, or both. Excluding these extreme cases, most estimates seem to suggest that biocrusts typically recover from disturbance in several years to a few decades, depending on the factors listed above. The operational definition of recovery can also be a complicating factor. Recovering disturbed biocrusts may attain an appearance similar to undisturbed biocrusts relatively fast, but the full recovery of biomass, diversity, composition and multifunctionality may take much more time. Another consideration when estimating recovery rate is that recovery is likely not to be linear, but instead works in pulses when climate conditions are good for growth, interspersed with long periods of slow or static growth (Weber et al., 2016).

The barriers to natural recovery are hypothesized to be hierarchical, and include active soil erosion, resource limitations, and propagule limitations; as these barriers are lifted, recovery may occur (Bowker, 2007). Biocrusts are often described as following a successional sequence as they recover. Light-pigmented cyanobacterial communities are often among the early colonizers, followed by dark-pigmented cyanobacterial communities, followed by either mosses, lichens or both (Weber et al., 2016). For the most part, this sequence is a series of addition of organisms rather than complete replacement, and the sequence may only attain the later stages where the environment permits later successional forms. Though this successional sequence is commonly reported from disparate localities, it is not universal. In some locations mosses are early successional taxa, whereas cyanobacteria can be late successional. Further, biocrusts of some ecosystems appear to have alternative states and successional pathways depending on the specific nature of the disturbance regime. It must be noted that most of what we know about natural recovery and successional pathways comes from studies that are not able to observe the complete pathway, so estimates of time to recovery and true trajectories are often incompletely known.

Assisted recovery

Assisted recovery of biocrusts is an active area of interest and research in which considerable advances have been made over the last 20 years (Weber et al., 2016; Antoninka et al., 2020). The goal of assisted recovery is to increase the rate of biocrust recovery and associated ecosystem functions through human intervention. Interventions can include methods to stabilize soils and retain biocrust propagules, enhance nutrient availability, increase water availability, propagule cultivation and subsequent addition, and combinations of the above. Interventions should be guided by specific recovery targets as well as the economic and technical constraints of the activities. Further, assessing the site conditions and addressing the barriers to recovery are critical first steps to ensure that the best interventions are chosen. Considerable progress has been made in methods to stabilize soil and retain propagules on site, as well as methods to cultivate biocrusts in the laboratory, greenhouse and field. Cultivation allows for biocrust inoculum to be produced on demand with lesser reliance on sourcing material from the field; this step is critical to the sustainability of inoculation interventions. Major barriers still to be fully addressed include success of cultured organisms in the field, storage of propagules, scaling up the areas that can be treated, and finally, guidance for land managers.

Management considerations

As our understanding of biocrusts as integral ecosystem components grows, biocrusts can increasingly be considered in land management plans. Key steps to integrating biocrusts into management activities include:

1. Monitoring the abundance, community, condition and function of biocrusts as indicators for the health and trend of landscapes (Belnap and Lange, 2003).
2. Identifying trends in the monitoring data to guide decisions such as site selection for conservation, restoration or construction projects or to trigger shifts in management strategies.
3. Educating the public on the importance of biocrusts and managing their land use behavior, for example limiting off-highway vehicle recreation to designated areas.

The requisite data for monitoring biocrusts across landscapes is becoming more widely available to support management activities. While remote sensing of biocrusts still faces many challenges due to the presence of vegetative overstories with similar reflectance, advances are being made in both coarse, large-scale monitoring with satellite imagery and finer-scale monitoring with unmanned aerial systems (Havrilla et al., 2020). Ground-based monitoring of biocrusts is also increasing, as with the US Bureau of Land Management's Assessment, Inventory and Monitoring (AIM) Strategy which, alongside other indicators, includes multi-year data on the abundance of biocrusts on soils (Herrick et al., 2021) and has been implemented across the western US. As biocrust monitoring at multiple scales becomes more widespread, land managers will have increasing access to important data that can guide their decision-making process.

Because they are a sensitive element of landscapes and ecosystems, loss or gain of biocrusts can signal the success or failure of a management or land use strategy to meet its goals. For example, large-scale soil conservation efforts, such as the Grain for Green

program in China, have found that altering land management regimes can dramatically reduce soil erosion (Gao et al., 2017). A major reason for and an excellent indicator of this landscape transformation was the widespread proliferation of biocrusts which strongly reduced erosion rates (Gao et al., 2017). Public land managers in the US are also starting to include the return of biocrust cover as a metric of successful recovery after disturbance. As more biocrust research focuses on land management decision support, the breadth of applications for biocrust monitoring in management plans may increase.

Educational outreach about biocrusts has taken many forms including interpretive signage in biocrust-rich recreation areas, workshops targeted toward land managers and recreation industry professionals, and programming in elementary schools. While these relatively targeted methods are effective at reaching their audience, more work is needed to ensure public support for incorporating biocrusts in land management. López-Rodríguez et al. (2020) call for the biocrust research community to adopt a “social-ecological research perspective” which prioritizes inter-disciplinary collaboration between researchers and non-academic stakeholders to advance the use of biocrust in conservation practices.

Conclusion

Biocrusts are a globally-distributed ecological community type composed of cryptogams and microbes found directly on the soil surface creating a distinctive thin, aggregated layer that is also photosynthetic. They are currently estimated to cover 12% of the land surface. Biocrusts are multifunctional, contributing to a wide variety of ecosystem functions such as soil stabilization, accumulation and maintenance of fertility, interception, retention and redistribution of water, among others. They interact with and influence the development and composition of other co-occurring assemblages such as those of vascular plants and soil microfauna. Thus, biocrusts are both widespread and highly influential to the functional state of the ecosystems that they occupy.

Despite the breadth of their niche and their impressive abilities to tolerate key abiotic stresses such as desiccation and UV exposure, they are vulnerable to physical disturbance, either due to natural disturbance regimes or human land use. Biocrusts are also vulnerable to climate change. Simultaneously, most ecosystems are warming and experiencing greater water evaporation from soils. Such changes are likely to impact biocrusts negatively by reducing their hydration time and therefore periods of activity. To reduce some of these negative effects on biocrusts and their functional contributions to ecosystems, it is necessary to consider the impacts on biocrusts in land management decision making. Currently, development of techniques to assist recovery of biocrusts after a disturbance is a major research theme. Researchers are learning to grow biocrusts for re-entry into degraded ecosystems to improve ecosystem function.

Since the early 2000s biocrust research is growing at a fast rate and becoming increasingly international as more scientists recognize the distinctive attributes and importance of these communities and their vulnerabilities. Knowledge gaps remain. For example, there are geographic gaps in our knowledge of biocrusts to fill and we do not currently have a complete understanding of the global roles of biocrusts in regulating the Earth system nor how to incorporate them into models. Nevertheless, new knowledge is accumulating quickly as new tools and perspectives are being applied (Rodríguez-Caballero et al., 2022), and each year we know substantially more than the last.

Abstract

One of the major challenges in microbial ecology is the inability to culture most microorganisms under laboratory conditions. Based on comparisons with culture-independent techniques, it is thought that less than 1% of microbial species has been isolated through standard cultivation techniques. Nonetheless, cultivation remains the only way to amplify the microbial material, fully characterize their functions and metabolism, predict their impact on an environment and validate phenotype predictions based on genomic analysis. This chapter describes traditional and novel culture-dependent techniques to isolate, grow and study soil microorganisms.

Glossary

Community-level physiological profiling (CLPP) A rapid method to assess the metabolic potential of a microbial community by simultaneously testing their growth with different carbon sources (i.e., substrate utilization patterns).

Culture medium Solution that contains all the necessary nutrients required to grow specific microorganisms or groups of microorganisms.

Culture-dependent methods All microbiological methods based on growing microorganisms by incubating them in a culture medium under controlled environmental conditions.

Culturomics High-throughput culturing of microorganisms based on testing hundreds of culture conditions to comprehensively identify strains or species in complex samples.

Diffusion chambers Devices to grow microorganisms in their natural environment by restricting their movement but allowing the diffusion of chemicals to and from the exterior.

Dilution to extinction Process where a sample is diluted until, on average, there is only a single viable cell left in a given dilution.

Flow cytometry A fluorescence-based method used to identify and quantify different cell types in a solution of heterogeneous cells.

Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) Technique used to identify microbes based on the comparison of their protein mass spectra with a database of known microbes and their protein mass spectral signatures.

Microbial culturing Process of growing microorganisms in a lab setting by inoculating them onto a previously sterilized culture medium.

Microfluidics Technology involving the manipulation of small volumes of fluids (e.g., in the range of microliters to picoliters) using channels on the scale of tens to hundreds of micrometers.

Most probable number (MPN) An indirect method to quantify viable microbial cells based on the serial dilution of a sample and the presence of growth at each dilution level.

Optical tweezers Systems consisting of a neodymium laser tightly focussed to a tiny region in space using a microscope objective as a lens.

Plate count A method based on the cultivation of microorganisms on a solidified culture medium in order to immobilize microbial cells and count the number of colony forming units (CFUs).

Pure culture A microbial culture containing a single kind of microorganism, which can be isolated from an environmental sample.

Single-cell manipulation Techniques used to selectively isolate individual cells, useful for isolating slow-growing or low-abundance microorganisms that would not be detected in enrichment cultures.

Key points

- Culture-dependent techniques applied to soil microbiology
- Basics of culture media (types and uses)
- Quantification of viable microorganisms
- Functional or physiological profiling
- Manipulation of single cells
- Improved culturing conditions and isolation via diffusion chambers
- High-throughput culturing or culturomics

Introduction

Microbial culturing techniques are among the oldest tools to study soil microbial communities, and they have revolutionized biology and biotechnology, leading to significant advances in fields such as medicine, waste management, and food science. Culture-dependent techniques have played an important role in identifying and characterizing new microbial species but are still low-throughput and time-consuming processes. One of the major challenges in microbial ecology is the inability to culture most microorganisms under laboratory conditions, as only a small fraction (<1% of species) has been isolated through standard cultivation techniques. This limitation leads to a phenomenon known as the “great plate count anomaly,” which refers to the relatively reduced number of microorganisms from a natural sample that can be grown in any culture medium compared to the cell counts observed using microscopy (Madigan et al., 2021). One of the reasons behind this limitation is the failure to mimic their natural growth environment and the lack of information regarding specific requirements in terms of nutrients, temperature, pH, and other environmental factors. Other reasons why microorganisms cannot be cultured in isolation are related to their need, in some cases, for the presence of another organism to survive (e.g., obligate symbionts). In environmental samples, microorganisms can also be present in very low abundance or in a dormant-like state, known as viable but nonculturable (VBNC), where visible growth is not achieved even if conditions are suitable for that particular organism.

In recent decades, genomics studies revealed that unculturable microorganisms represent a large pool of novel species and biotechnological potential. Omics tools have an enormous potential to explore the structure and function of complex microbial communities, but they still present challenges due to the complexity of the obtained datasets and the considerable cost involved in carrying out multiple omics analyses. Culturing still remains the only way to fully characterize microbial functions and metabolism, validate phenotype predictions based on genomic analysis and generate microbial biomass. Realizing the crucial importance of bringing more microbial species into cultivation, different techniques have marked the rebirth of culture-dependent approaches by trying to better understand the specific requirements of each microorganism and mimic their natural growth conditions.

Microbial culturing and culture media

Microorganisms can be grown in the laboratory by inoculating them on a previously sterilized culture medium while maintaining aseptic conditions during the whole process. Culturing allows to obtain pure cultures by isolating and growing cells from a single microorganism. Culture media are solutions that include all the nutrients necessary to grow a particular microorganism or group of microorganisms, and they can be liquid or solid. Solid media are obtained by adding agar to the solution and they are typically formed in a Petri dish. These media have the advantage of immobilizing microbial cells, allowing them to form visible growth colonies which can be used for characterization and counting, as well as isolation. In contrast, liquid media do not permit separate colonies to be distinguished but they allow for rapid growth and hence can be used for enrichment or resuscitation. A broad classification of media separates them into those that are defined, which means they contain known amounts of specific organic or inorganic chemicals, and those that are complex or made from digests of microbial, animal or plant products (e.g., yeast extract, beef extract and tryptic soy broth, respectively). Minimal media are those that contain the minimum amount of nutrients possible for growth and are useful for growing oligotrophic organisms that would not be able to grow in a nutrient-rich medium. Previous information from targeted organisms must be known to determine their minimal media requirements. In terms of the organisms able to grow in them, culture media can be general (i.e., allowing the growth of several different species) or selective, tending toward the requirements for a specific organism, promoting its growth but inhibiting or preventing the growth of undesired organisms (e.g., using antibiotics or other selective agents, or via changes in pH or osmotic conditions). Enrichment media, on the other hand, are liquid media that promote a particular type of organism from a complex mixture (e.g., soil sample) with or without the use of inhibitors (selective or elective, respectively). A special type of solid culture medium, known as differential, allows the distinguishing of different microorganisms growing together by producing specific colony morphology (e.g., color). This is usually achieved by including an indicator (e.g., pH indicator) that responds to changes in the medium due to different substrate utilization or production of specific compounds. Besides the culture medium, other important factors that are taken into consideration during microbial culturing are growth conditions, such as incubation temperature, oxygen levels, pH and osmotic conditions.

Enumeration of viable microbial populations: Plate count and most probable number

Enumeration methods to determine viable soil microorganisms may be accomplished by direct (e.g., standard plate count) or indirect (e.g., most probable number or MPN) techniques. Yet, it is important to emphasize that bacteria classified as viable in reality only include those capable of growing on the media used and with the incubation conditions employed. The fundamental principles of both these methods are (i) creating a series of dilutions of the original sample, (ii) dispensing an aliquot to a growth medium, (iii) incubating under appropriate conditions, and (iv) counting the developed colonies or detecting the presence or absence of growth (Germida and de Freitas, 2008). Both methods are inexpensive and can give a qualitative or quantitative assessment of the number of viable microorganisms in a sample. However, these techniques are often time consuming and rely on morphological (e.g., colony shape and size) and biochemical (e.g., Gram stain) methods, which may have a very severe bias. Therefore, expanding the repertoire for microbial identification also relies on other methods based on carbon source utilization, synthesis of lipids, and oxygen requirements.

The standard plate count method uses Petri dishes with solid culture media, which allow to count the number of colony forming units (CFUs) per milliliter of diluted sample plated (Pelczar et al., 2002). The term CFU is used because two or more cells can be clumped together forming a single colony, even though the assumption is that each colony is formed by a single organism. Plate counts can be done using the spread-plate method (Fig. 1), where the diluted sample is spread on solidified agar, or the pour-plate method, where molten agar is poured on top of the sample. To avoid errors, the number of colonies cannot be too large or too small, so a standard practice is to prepare and plate several 10-fold serial dilutions of the original samples and count only plates that have 30–300 colonies (Fig. 1).

The MPN method is used to estimate microbial population sizes when counting single viable cells or colonies is not possible. The liquid culture media used in MPN allow a greater nutrient exchange and is more suitable for specific groups of microorganisms that will not readily grow on solid agar (e.g., a variety of protozoa, autotrophic-nitrifying and sulfur-oxidizing bacteria) (Germida

Fig. 1 Representative diagram of the spread-plate method. In this technique, the soil sample is diluted (1:100) in a specific buffer [often phosphate buffered saline (PBS) is used], and then subject to 10-fold serial dilutions ①. Each dilution is then plated in solid culture medium (in duplicate or triplicate) ② using a specific agar medium based on the type of microorganism to be quantified. An inoculum volume of 0.1 mL should be used to ensure spreading, absorption, and proper counting. The inoculum should be spread shortly, using flame-sterilized glass or metal spreader. After incubating under controlled conditions ③, the plates should reflect the predictable drop in colonies number based on the serial dilutions. Plates from dilutions yielding 30–300 colonies should be counted, and the results expressed as CFUs g^{-1} of dry soil (colony forming units per gram of dry soil) ④. Adapted from Pepper IL and Gerba CP (2015) 'Cultural methods', in Pepper IL, Gerba CP, and Gentry TJ (eds) *Environmental Microbiology*. 3rd edn. Academic Press, pp. 195–212, created with BioRender (<https://biorender.com/>).

and de Freitas, 2008). This method also starts with serial dilutions of the initial sample, and each dilution is inoculated in liquid medium with 5–10 replicates. Each tube is classified as a positive or negative based on the presence of growth (e.g., turbidity, gas, substrate utilization) and the number of positive/negative tubes per dilution is used to calculate using publicly available MPN tables (Woomer, 1994). Some disadvantages are that it is time-demanding and less precise than plate counting.

Community-level physiological profiling

The main principle of community-level physiological profiling (CLPP) is to characterize specific organisms or groups of organisms based on their ability to metabolize different substrates. Microorganisms are cultivated on microplates containing different carbon sources (e.g., carbohydrates, amino acids, amines, carboxylic acids, and polymers) and wells without a growth substrate are used as a control (Garland, 1997). The technique uses a redox system, where tetrazolium violet is frequently used as an indicator of oxidation. During the period of incubation, soil microorganisms oxidize substrates in the plate wells, while simultaneously reducing the colorless tetrazolium dye to a violet formazan. These color changes are measured spectrophotometrically, based on absorbance (i.e., optical density), using an automated plate reader that interprets the results and compares them with a known database. The inoculation of soil solutions directly into plates allows for a rapid and convenient tool to obtain physiological profiles of whole microbial communities (Weber and Legge, 2010). Yet, it is important to note a few limitations. For example, due to cross-species interactions and different nutrient requirements, it is impossible to know precisely, which groups of microorganisms contribute to substrate use on a plate. Moreover, there are biases among the different abilities of bacteria to use the substrates, where non-culturable or slow-growing microorganisms, incapable of growing in such conditions, are not included in the analysis. Other variants of this methodology, including culture-independent ones, are described in Chapter 00115 Studying soil microbial function: Culture-independent approaches.

Single-cell manipulation and isolation

In the techniques mentioned above, isolation of targeted organisms is most often achieved by dilution to extinction. This is where a sample is diluted until, on average, there is only a single viable cell left in a given dilution. In single cell manipulation systems, individual cells may be selectively isolated, rather than leaving the choice of cells being investigated to chance. This is particularly useful for isolating slow-growing microorganisms or organisms present at such low numbers that would not be detected in enrichment cultures.

Flow cytometry

Flow cytometry (FCM) is a well-established fluorescence-based method in medical science that is used to identify different cell types in a solution of heterogeneous cells. In microbial ecology, FCM has been gaining significant attention as a direct and rapid method to assess soil bacterial abundance and analyzing microbial cells at the single-cell level (Frossard et al., 2016). The method first separates microbial cells from soil particles by: (i) detaching the cells by mechanical (i.e., shaking or sonication) or enzymatic treatments, and (ii) separating these cells from soil organic and inorganic particles (i.e., by filtration or centrifugation) before quantification. Then, microbial cells are stained with fluorescent markers (e.g., SYBR Green and acridine orange) and analyzed in a flow cytometer so that the light is absorbed and then emitted in a band of wavelengths (Khalili et al., 2019). Hence, an efficient separation method maximizing cell recovery while reducing interference from background debris is critical to the procedure. A flow cytometry analyzer can distinguish background noise signal caused by non-biological particles, and it uses relative size, fluorescence intensity and wavelength to allow the quantification of many thousands of cells per second. Although the fluorescent signal can be masked by nonspecific dye binding and auto-fluorescence, FCM is more accurate than epifluorescence microscopy-based (EPM) enumeration in terms of human biases, detection of small cells (<0.5 μm) or cells hidden under soil particles. Moreover, it is less time- and labor-intensive, which facilitates the analysis of larger sample sizes (Deng et al., 2019).

Optical tweezers

The main mechanisms of optical tweezer (OT) systems consist of a neodymium laser tightly focussed to a tiny region in space using a microscope objective as a lens. This region becomes an optical trap for small objects such as a biological cells or organelles. Trapping a single cell is possible because the laser beam creates a force that pushes down on a cell and holds it in place (Eriksson et al., 2007). The system may also contain a glass capillary tube with a predetermined breaking point (i.e., notches in the tube wall to determine the breaking location), which is used as a separation chamber between a suspension of mixed microbial population and a fresh sterile medium. The capillary creates a linear microchannel into which single cells could

be optically manipulated. When the laser beam is moved by a computer-controlled microscope stage, the trapped cell moves along with it. With this movement, a single cell from the mixed culture is then separated into the fresh medium section of the tube. The capillary is then broken at the predetermined breaking point, where the single cell is transferred to a new tube of sterile medium (Madigan et al., 2021). This technique therefore allows microbes to be cultivated by eliminating the competition of faster growing organisms. Additionally, the forces applied in the optical trap can be measured as well, which opens up a broad range of possibilities in detecting the environmental effects on microbial cells, such as cell elasticity and flagellar motion. For example, a few studies have combined OT with microfluidics to move microbial cells from one microenvironment to another. The cells were exposed to these different environments, where the adaptation to changes in nutrient concentrations or responses to osmolarity can then be studied (Kelothe et al., 2018).

Diffusion chambers

One effective strategy to improve microbial cultivation methods is to mimic their natural environment in the laboratory. For this purpose, diffusion chambers allow microorganisms to grow into pure culture by using the required chemical components from their natural environment (Bollmann et al., 2007). First, soils are serially diluted, mixed with sterile agar and inoculated between two semipermeable membranes. The chambers are then placed on the same soils from which dilutions were carried out and moistened if necessary. The membranes are permeable to molecules of various sizes, thus allowing for the diffusion of necessary elements from the soil into the inner chamber, but also acts as a barrier restricting the passage of microbial cells from the chamber to the external environment (Pham and Kim, 2012). This permits microbial cells trapped in the inner chamber to have access to their naturally occurring growth components (e.g., oxygen, nutrients, and metabolites) and provides a natural environment for microbe-microbe interactions to occur. After incubation, diffusion chambers are opened, the biomass is collected and, if necessary, transferred to new sterile chambers to enhance recovery of environmentally relevant isolates.

Diffusion chambers improve microbial recovery and *in vitro* cultivation of otherwise poorly cultivable species when compared to conventional plating. But one limitation is its relatively small throughput, producing hundreds of microcolonies from multiple species which needs laborious separation under a microscope. Therefore, the isolation chip or “ichip” has been designed based on hundreds of miniature diffusion chambers (Nichols et al., 2010). Each diffusion “minichamber” is loaded with a single cell that results in a culture that is monospecific. Yet, for growth, some microbial species require a close proximity to their synergistic partner(s), such as hydrogen-producing bacteria and methanogenic archaea. Thus, having these two partners on different sides of the membrane will compromise this synergy and the recovery of these species. On the other hand, the simplicity of the ichip construction, the ease of its application and the high recovery of microorganisms are great advantages of this method. After one round of *in situ* cultivation, the colonies that remain “uncultivable” can then be passed through more rounds, with each cycle leading to isolation of additional species (Berdy et al., 2017).

Culturomics

Culturomics identifies microbial species using high-throughput culturing with hundreds of culture conditions and matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) (Fig. 2) (Lagier et al., 2012). This technique emerged from studies on the human gut microbiota, with the aim of optimizing culture conditions of “yet to be cultured” organisms and to address the shortcomings of metagenomics, where some rare taxa do not have adequate sequencing coverage to be detected (Lagier et al., 2012). In addition, culturomics yields information about live microbial communities, whereas metagenomics is unable to distinguish between DNA from live or dead organisms. Culturomics led to the recovery of microbes from environments that were thought to be uninhabitable, and it is now expanding to other fields such as microbial ecology (Sood et al., 2021).

The first step of culturomics is to divide an environmental sample into different culture conditions (e.g., culture media, antibiotics and oxygen levels) and then generate pure cultures of microbes (Fig. 2). These conditions are designed to suppress fast growers and improve the isolation of fastidious microorganisms. Once isolates are obtained, the next step is identification, where MALDI-TOF mass spectrometry is used as a simple and fast (<1 h) method that relies on the comparison of the isolate’s protein mass spectra with a database of microbes and their protein mass spectral signatures. If this identification fails, colonies may be analyzed through ribosomal RNA sequencing. Finally, if there is less than 98.65% similarity to the closest official strain, the isolate could be identified as a putative novel species. However, one important limitation of culturomics is the major laboratory workload and the inability to test as many samples at the time as other methods (e.g., metagenomics), although, in some cases, the number of culture conditions can be optimized.

Since culturomics is an approach based on the recovery of the greatest number of microbial species present in the sample, the results obtained can only be qualitative but not quantitative. However, this limitation can be easily overcome by combining it with quantitative PCR. Moreover, culturomics is highly complementary to metagenomics, where one can enhance the output of the other (Table 1). Together they can be used to describe the composition of different microbiomes more exhaustively (Lagier et al., 2018).

Fig. 2 Overview of culturomics pipeline from microbial sampling to identification. Culturomics uses high-throughput culturing of microorganisms obtained from environmental samples ① on many different types of media and with many different culture conditions ②, to maximize their recovery. In the original methods, microorganisms are isolated to obtain pure cultures ③ so that they can be identified using protein spectra generated by MALDI-TOF mass spectrometry ④. Protein spectra generated are compared to a database of spectra correlated with known microorganisms. Mass spectrometry is a much faster and much cheaper way to identify microorganisms when there are hundreds to thousands of pure cultures to identify. However, if spectra are unidentified in the database and a new species is suspected, sequencing can be used to confirm the identification ⑤. Created with BioRender (<https://biorender.com/>).

Table 1 Limitations and advantages of metagenomics approaches vs. culturomics.

	Metagenomics	Culturomics
Limitations	DNA extraction: extraction protocols differ in cell lysis efficiency with a major impact on the recovery of genomic content from difficult-to-lyse organisms. These limitations could lead to significant differences in diversity and taxonomic distribution Amplification (amplicon sequencing): highly dependent on the choice of primers and on the efficacy of DNA polymerases (e.g., samples with high GC content are not amplified as efficiently) Bioinformatics: variations in the methodology used (pipelines, clustering, taxonomic assignment) and difficulty in discriminating between species due to short amplicon length (amplicon sequencing) Viability: failure to discriminate if the sequences belong to active, quiescent or dead microorganisms Depth: difficulty in detecting microorganisms at very low concentrations (depth bias) Low taxonomic resolution: cannot identify novel species and often relies on comparisons with databases of known genomic sequences of microbial cultures	Sample material: steps to divide the sample and establish different culture conditions may require more sampling material to work with Recovery: the discovery of a novel or “not yet cultivable” species may still not be achieved despite the different conditions established (e.g., novel species that could only grow in the presence of other community members) Growth conditions: can still be difficult to source or formulate. Dealing with multiple organisms at a time with different growth rates and nutrient requirements can be challenging Time: major laboratory workload is often required, which limits the ability to test many samples at a time Quantification: results are only qualitative and not quantitative since it targets the maximum recovery of microbial species Function and metabolism: does not provide information on enzymatic capabilities, only taxonomic identification

Table 1 (Continued)

	Metagenomics	Culturomics
Advantages	<i>Processing a large number of samples:</i> allows the analysis of thousands to tens of thousands of genes or gene regions simultaneously <i>Relatively easy to assign taxonomic classification:</i> uses several validated tools and curated databases (variety of software available for analysis) <i>Detection of uncultured microbes:</i> metagenomics considers both culturable and unculturable organisms where the latter can be grouped without taxonomic assignment <i>Time:</i> sample preparation, analysis and comparison of large cohorts in record time <i>Functional Analysis:</i> the function of microbial communities can be inferred by shotgun sequencing	<i>Detects only viable bacteria:</i> avoids false discovery rates and over-representation of species by the identification of DNA from dead organisms <i>Recovery of rare species:</i> can detect minority populations by suppressing majority populations and selectively promoting growth of fastidious microorganisms at lower concentrations <i>Discovery of new species:</i> sequences isolated by culturomics can be compared, at the species level, to those generated by previous metagenomic studies, thus facilitating process for new species announcement <i>Costs:</i> relatively inexpensive since taxonomic identification by MALDI-TOF MS requires a low level of training and lower costs compared to 16S rRNA sequencing <i>Experimental testing:</i> increases the availability of strains for in vitro/ in vivo studies and facilitates the discovery of new targets and functions within the microbiome

Concluding remarks

Culture-dependent approaches provide valuable information about soil microbial communities, as they allow for the isolation and characterization of specific microorganisms, providing means to study their growth requirements, physiological and biochemical properties, as well as interactions with other microorganisms. Even though culture-dependent approaches have lost popularity with the advent of culture-independent approaches (e.g., genomics, transcriptomics and proteomics), they are now seeing a re-birth as we acknowledge their importance for characterizing microorganisms and their functions. Part of this re-birth was in fact greatly influenced by culture-independent techniques, which provided valuable information on how to grow so-called “unculturable” microorganisms in the laboratory. As technology advances, new methods for the isolation and characterization of soil microorganisms continue to emerge, offering new opportunities to understand the role of these communities in ecosystem functioning. While these methods still have limitations (e.g., bias toward easily culturable microorganisms, potential for isolating non-representative microorganisms, specific growth requirements), they remain a valuable tool in the study of soil microbiota. Most likely, it will be the combination of both culture-dependent and -independent approaches that will significantly advance our understanding of soil microbial communities, their functions and their relationship with ecosystem processes. A more complete understanding of these complex communities will be key to develop potential applications in sustainable agriculture, ecological restoration and bioremediation.

Abstract

Soils are known to host remarkably diverse microbial communities. The first tools to investigate these communities relied on culture-based approaches and could not detect the vast majority of the microbial community. Over the last few decades, numerous culture-independent methods have been developed to improve the characterization of microbial communities. Most notable among these methods is the advent of PCR, clone library construction, high-throughput sequencing, and metagenomics, with high-throughput sequencing and metagenomics being the approach currently most used by microbial ecologists.

Glossary

Bioinformatics Interdisciplinary field based on computer science, statistics and mathematics to analyze and interpret biological data such as DNA sequencing data.

Biomarker A measurable and characteristic compound or molecule used to identify or quantify the presence or abundance of a specific organism or type of organism.

Community profiling Techniques used to identify and quantify microbial structure in terms of the organisms present and their relative abundance.

Culture-independent methods Techniques to study microorganisms without growing them in culture media.

Fingerprinting Techniques used to distinguish between different organisms based on their DNA.

Fluorescent labels Chemicals that emit light when excited by a specific wavelength of light which are added to nucleotides for detection in different methodologies.

Gel electrophoresis Technique used to separate DNA fragments based on their size and charge.

Metagenome The collective genetic material present in an environmental sample, consisting of the genomes of many different organisms.

Microbial abundance Number or count of microorganisms in a given environment or sample.

Microbial biomass Total mass or weight of living microorganisms in a given environment or sample.

Plasmid Small circular piece of DNA that can replicate independently of the main chromosome in bacteria.

Pyrosequencing DNA sequencing method that uses detection of pyrophosphate release from nucleotide incorporation to determine the sequence of a DNA molecule.

Read length next-generation sequencing (NGS) term referring to the number of base pairs (bp) sequenced from a DNA fragment.

Sequencing adapters Oligonucleotides or short DNA fragments (~80 bp in length) added to the end of DNA fragments for sequencing, which allows the sequencing of multiple samples in a single high-throughput sequencing run.

Sequencing coverage Proportion of a genome that is represented by sequence reads in a sequencing dataset.

Sequencing-by-ligation DNA sequencing method that uses ligation of short oligonucleotides to a DNA template.

Sequencing-by-synthesis DNA sequencing method where nucleotides are added one at a time to a growing DNA chain, with each addition detected and recorded.

Ultrastructural studies Studies based on the examination of biological specimens at a high magnification level using electron microscopy with the goal of visualizing cellular and subcellular structures at a much higher resolution than using traditional light microscopy.

Introduction

The extremely diverse and abundant soil microorganisms include members from the three life domains: Bacteria, Archaea, and Eukarya. These microbes do not exist in isolation but thrive in communities. Understanding and describing the huge diversity of soil microbial communities requires methodologies that may allow for a comprehensive, broad view of all organisms present in a soil sample. The first methods to enumerate and identify soil microbes were culture-dependent, which were eventually shown to account for less than 0.1–1% of the community. The progression of soil microbial ecology as a scientific discipline is undeniably linked to the emergence of comprehensive, faster, specific, and more sensitive culture-independent molecular techniques, which have allowed new insights into the diversity, abundance, and activity of soil microbial communities. These techniques mostly focus on analyzing genetic-coded information from soil-extracted nucleic acids (DNA or RNA) to assess the diversity of soil microbial communities. In the last two decades, the development of high-throughput sequencing methods for nucleic acid sequencing has made possible the taxonomic profiling of soil microbiota at high resolution. In this chapter, we describe the utility and methodological basis of traditional and current culture-independent approaches used to study soil microbial community structure.

Traditional techniques to study soil microbial abundance and biomass

There are several ways to estimate the abundance and biomass of microbial communities in soil. Techniques can be either direct or indirect, may target a whole community or just a subgroup, and can capture microorganisms under different physiological conditions (e.g., active, dormant, and sometimes dead). Before the advent of culture-independent methods, enumeration techniques like microscopy and culturing were commonly used to quantify the abundance of microorganisms in a soil sample. These methods have been replaced by more accurate and less labor-intensive techniques, especially in the field of soil microbial ecology where the subject of study is the whole microbial community.

Microbial biomass represents the mass of living microorganisms present in the soil, and, as such, it is a fraction of soil organic matter. Given the simplicity and robustness of the soil microbial biomass assessment methods, it has widely been used as an indicator of soil quality and health, and thus an indirect indicator of the soil's functional status. There are several methods to quantify both soil microbial biomass and abundance, most of which rely on the extraction and quantification of a compound or biomarker, or physiological parameters such as the respiratory response of the community.

Enumeration techniques using microscopy

Microscopy allows for direct counts of microbial cells. It usually involves preparing a 1:5 soil: water suspension, selective staining (e.g., acridine orange for fluorescence microscopy), and counting the bacterial cells or fungal mycelia. Compared to culture-dependent techniques (e.g., plate counts), microscopy is direct and not restricted to the very small fraction (~1%) of the soil microbial community that is represented by culturable microorganisms. Hence, it is not surprising that enumeration via microscopy yields larger numbers of bacteria than culturing methods. Still, microscopy also presents its challenges, such as being more suitable for bacteria than fungi, because of their simpler unicellular morphology. Depending on the principle of acquiring images, microscopy may be differently catalogued. Light microscopy is ideal for naturally pigmented cells. However, most cells are

not pigmented, so they need to be thermally killed (i.e., fixed) and stained with dyes to facilitate contrast and visualization. Alternatively, phase contrast microscopy allows imaging of live cells in black and white. With electron microscopy, beams of electrons, instead of diffusing light, focus on the specimen. A more advanced type of microscopy, fluorescence microscopy, uses laser generators to supply incident light of a defined wavelength to the specimen, which then generates defined wavelength fluorescence; this can be employed to repeatedly capture live cell images and thus visualize time lapses of changes in living cells. These methods in microscopy provide high-resolution images and are effective in ultrastructural studies of soil particles and microorganisms. Since there are several complexities involved in soil preparation, no universal microscopy technique applies to all microbes in the soil.

Biomass: Substrate-induced respiration

Soil microbial biomass can be determined using physiological methods, such as substrate-induced respiration (SIR), fumigation-incubation, or oxygen-uptake assessment. SIR quantifies the respiratory response of the active fraction of the aerobic and heterotrophic microbial community upon being supplied with defined carbon substrates. These respiratory response measurements can be converted to units of total microbial biomass by calibration against fumigation-based techniques. Respired CO₂ can be measured via titration or by chromatographic analysis of headspace gas. An empirically determined conversion factor of 40.04, estimated from the correlation between SIR and fumigation techniques, is commonly used to convert the rate of substrate-induced CO₂ to total microbial biomass. A standardized protocol to quantify soil microbial biomass via SIR is described in ISO 14240-1:1997.

Biomass: Fumigation-based techniques

Fumigation-incubation, also based on respiratory responses, is a direct measurement of soil microbial biomass. Here, soil samples are fumigated with chloroform to kill microbial cells, inoculated with a non-fumigated soil suspension aliquot, and then incubated for 24 h. It is assumed that the newly inoculated cells will consume the dead biomass from fumigated samples and respire CO₂. The difference in CO₂ production between fumigated and unfumigated samples is thus assumed proportional to the dead biomass in the fumigated sample and can be expressed as microbial biomass carbon using a conversion factor of 0.45. Microbial biomass nitrogen can be calculated by extracting and quantifying ammonium instead of measuring respired CO₂. A similar approach is used in the fumigation-extraction method, where organic C from both fumigated and non-fumigated samples is extracted using 0.5 M K₂SO₄ and quantified, and microbial biomass carbon is estimated as the difference between both. The fumigation-extraction approach also allows the extraction and quantification of N and P, to estimate the size of microbial pools for these two elements. The standardized protocol for the fumigation-extraction method is described in ISO 14240-2:1997.

Biomass: Biomarker-based techniques

Biomarkers are simply biochemical compounds found in cells, but sometimes also present extracellularly. For biomarkers to be reliable estimators of biomass, ideally, they should only be present at a relatively constant concentration in living cells, quickly degrading after release from dead cells. A good example of bioindicators of microbial biomass is total, extractable fatty acid methyl esters (FAMES) or, more particularly, methyl esters of phospholipid fatty acids (PLFAs) (Li et al., 2020). These lipid biomarkers are associated with vital functions, such as storing energy and signaling, and thus their abundance and profiles are indicators of living soil microbial communities. FAMES comprise PLFAs, as well as neutral lipids and glycolipids. The PLFA fraction is constituted of polar lipids from the cell membrane lipid bilayer that have a very short life in soil once the cell dies. Thus, PLFAs represent only viable microorganisms.

An alternative approach is to extract total DNA and quantify it as an estimator of microbial biomass, using a method that maximizes DNA yield (ISO 11063:2012) as opposed to commercial DNA extraction kits (Petric et al., 2011).

A key limitation of these techniques is that extracted biomarkers might not be derived only from living organisms. Moreover, variable extractability can make the techniques less accurate.

Biomass of specific microbial groups

Most of the methods described above target microbial communities without distinction. Nevertheless, some biomarkers are found only in certain microbial groups and are thus suitable for targeted quantification. An example widely used is ergosterol, a membrane sterol found in most fungi but rarely in other microorganisms. Similarly, muramic acid and diaminopimelic acid were used to quantify prokaryotic biomass. Both FAMES and PLFAs have also been used to quantify specific groups such as saprophytic fungi, arbuscular mycorrhizal fungi, and bacteria (and within them Gram-positive, Gram-negative, anaerobic bacteria, cyanobacteria, etc.) (Frostegård et al., 1996). Alternatively, selective inhibition using antibiotics can be coupled with biomass measurements like SIR to estimate the biomass of bacteria (e.g., cycloheximide inhibits eukaryotes) or fungi (e.g., streptomycin inhibits prokaryotes). However, the level of suppression of the non-target group is variable with these inhibition methods.

PCR-based techniques to detect and quantify specific microbial groups

Polymerase chain reaction (PCR) methods like real-time quantitative PCR (qPCR) and digital PCR (dPCR) allow for an estimation of the abundance of specific microbial groups in a soil sample by amplifying a targeted indicator gene sequence. These methodologies are rooted in the assumption that each cell has an approximately equal count of the targeted indicator gene. The basic steps of PCR involve cycles of DNA denaturation, primer annealing, and extension (i.e., DNA polymerase synthesizes new target DNA strands). Nucleotides, Taq polymerase, DNA templates, and primers specific to the target genes are involved in the amplification of a small, specific segment of DNA. The cycles are repeated several times producing more than one billion exact copies of the initial DNA template.

The qPCR method uses fluorescence to recurrently quantify the amplified product after each PCR cycle, instead of a single end-point measurement (Heid et al., 1996). A variant of qPCR is reverse transcription qPCR (RT-qPCR), which allows work with RNA templates and thus quantifies RNA transcripts instead of gene copies. This is done by adding an initial step where RNA is reverse transcribed into complementary DNA (cDNA). Both qPCR and RT-qPCR rely on fluorescence intensity responses proportional to the gene copies or transcripts per unit reaction volume. A large number of copies makes quantification easier. If the amplification rate is known, and amplification inefficiencies are also known, then the final counts of the copies of the templates are proportional to the starting counts. The two detection chemistries used in qPCR are double-strand (ds) DNA-binding molecules and fluorophore-labeled short strands of DNA (oligonucleotides) that can serve as the starting point (i.e., primers) for amplification of a target sequence. For qPCR, SYBR Green is the most commonly used dsDNA-binding fluorescent dye. However, SYBR Green can bind to nonspecific PCR products resulting in overestimation. Oligonucleotides, can be modified by attaching a fluorophore at one end (i.e., fluorescent molecule at the 5' position?) and a fluorescence quencher at the other end (the 3' position). These are called TaqMan probes. If the probe is intact, then the proximity of the quencher to the fluorophore inhibits fluorescence. As the DNA strands are synthesized and the double strand DNA is produced the TaqMan probes are cleaved during hybridization and thus the quencher is separated from the fluorophore allowing it to fluoresce. As more copies of the target gene sequence are produced, the intensity of the fluorescence increases proportionally, allowing a direct quantification. Compared with SYBR Green, TaqMan-based detection is highly specific and involved in more applications, such as multiplexing, single nucleotide polymorphism (SNP) genotyping, copy number variation, pathway analysis, microRNAs, and protein analysis.

Digital PCR (dPCR) is a variation that relies on the same chemistry as the qPCR. However, for dPCR, the sample is diluted and partitioned into multiple subsamples on plates. Dilution purifies the target from inhibiting compounds, and the number of partitions improves precision. The partitioning ensures that the detection limit is enhanced as the small reaction volume increases the concentration of the target molecule. This makes dPCR useful for targets with only a small abundance, and applications in complex environments. Digital PCR platforms for partitioning can be classified as droplet-based (droplet digital PCR or ddPCR) and chamber-based (chamber digital PCR or cdPCR). The cdPCR utilizes physical structures (i.e., microfluidic chambers) as partitions, whereas ddPCR utilizes a water-oil emulsion droplet system that can generate millions of suspended droplets acting as partitions. After end-point amplification, any fluorescence is detected in droplets, with results digitized as 0 and 1 for negative and positive droplets, respectively. Using the Poisson distribution law, the fraction of positive droplets are converted to the number of molecules in the initial sample, using absolute quantification (standard curves not needed).

Fluorescence in situ hybridization (FISH) to identify specific microbial groups

Fluorescence in situ hybridization (FISH) is a technique that uses fluorescent probes (i.e., RNA or DNA oligonucleotides) that are complementary to a target sequence in a cell, to detect and identify specific groups or organisms in the sample. Common target sequences are the 16S or 23S rRNA genes, or mRNA for gene expression studies. A fluorescent dye is attached to the probe, so it can be visualized in situ using epifluorescence, a form of fluorescence microscopy. The basic steps of the FISH procedure involve denaturation, hybridization, probe detection, and analysis. Over the years, improvements in the specificity, sensitivity, and resolution of the FISH technique together with advances in fluorescence microscopy have resulted in the diversification of the protocol into various procedures that have increased our knowledge of the chemical properties of nucleic acids. For example, a variant suitable for gene expression studies or phylogenetic studies of microorganisms that are slow-growing or of small abundance is the catalyzed reporter deposition-FISH (CARD-FISH). In CARD-FISH, the probe does not have a fluorophore attached but the peroxidase enzyme, so that after hybridization it can be treated with a fluorescent labeled substrate of this enzyme. Other related techniques are fiber-FISH, useful for mapping genes, and rainbow-FISH for the detection and quantification of at least seven different microbial groups in a microscopic field. An in silico version of this technique is e-FISH, a BLAST-based simulation program useful as a bioinformatics tool.

Microbial community profiling using fatty acids-based approaches

The FAME and PLFA techniques described above can also be used for characterizing soil microbial community structure. For example, these techniques have been used to evaluate contrasting ecosystems or agricultural management practices, or the effect of biotic or abiotic stresses or disturbances. Both FAME and PLFA are rapid, sensitive, inexpensive techniques which use alkaline reagents to extract fatty acids from soil converting them into FAMEs. Based on the presence of unique fatty acid markers in different

microbial groups, these techniques allow the detection of specific microbial groups, such as Gram-positive and Gram-negative bacteria, actinobacteria, arbuscular mycorrhizal fungi (AMF), or saprophytic fungi. Specific fatty acids are usually detected and quantified using gas chromatography–mass spectrometry (GC–MS), based on structural criteria, such as the number of carbon atoms, or the number and location of double bonds. Although both PLFA and FAME share the same set of microbial FAME biomarkers, both methods differ during lipid extraction, separation, and transesterification. Whereas the FAME method extracts PLFA, glycolipids, and neutral lipids together, the PLFA methodology elutes and discards the last two fractions to purify only polar lipids. As mentioned earlier, because phospholipids have a short turnover time once the cell dies, they provide information on living organisms. A recent study also found that, despite having a higher cost and complexity than FAME, PLFA was more sensitive to changes in soil physicochemical properties (Li et al., 2020). Some fatty acids have been considered as indicators of physiological stress. A major limitation of these methods is that many fatty acids are common to several microorganisms, so they can be variably produced by diverse organisms under the same environmental conditions. This limits the resolution of FAME or PLFA profiles and makes their interpretation challenging (Frostegård et al., 2011).

Microbial community profiling using traditional molecular techniques

As mentioned in the previous sections, microbial ecology has been revolutionized in the last few decades, as emphasis has shifted from identifying individual microbes by culturing techniques to advanced methods employed for the assessment of natural communities. The analysis of molecular, DNA-based methods that involve cloning and sequencing of DNA fragments or amplification of target genes using PCR are some of the various approaches to community profiling (Nocker et al., 2007; Hirsch et al., 2010). Genetic profiling methods, such as denaturing gradient gel electrophoresis (DGGE), temperature gradient gel electrophoresis (TGGE), and automated ribosomal intergenic spacer analysis (ARISA), were among the first methods to be applied in the study of microbial composition and diversity. However, from the start of the 21st century, the rapid development of sequencing technologies has revolutionized the study of soil microbial communities and most of these technologies have been superseded.

Hybridization-based methods: Microarrays

In environmental microbiology, microarrays (or microchips) are used to characterize the microbiome (e.g. PhyloChip via phylogenetic oligonucleotide arrays) or to identify gene expression (e.g. GeoChip via functional gene arrays) of microbes in samples (Letowski et al., 2003; He et al., 2007). Microarrays use hybridization of either oligonucleotide probes or cDNA with target DNA or RNA sequences that have been tagged with fluorescent labels. The oligonucleotide probes are selected based on what is expected to be found or targeting organisms or functional genes of interest. When hybridization occurs, the fluorescent label is turned on indicating the presence of the feature of interest. Microarrays can be incredibly useful as they offer a high-throughput alternative (thousands of features can be assessed at a time) that is faster and costs less than sequencing. They are also good for detecting rare taxa in environmental samples and, depending on the probes used, can give a species-level identification of taxa. However, their hybridization technology can lead to false positives from unspecific complementary strand binding. Another limitation is that relatively large quantities of DNA or RNA are needed for hybridization to work.

Clone library construction methods

In the field of recombinant DNA technology, gene cloning has emerged as one of the most important developments of all time (Rougeon et al., 1975). The first phase in cloning a specific gene involves the construction of cloned DNA fragments, DNA library or gene libraries containing the gene of interest. Then, the DNA fragment that contains the target gene is inserted into purified DNA genome or a plasmid (cloning vector). Once cloned into the vector, sequencing of the insert produces the highest phylogenetic resolution and species identification can be achieved by using sequence databases. Sequencing of clone libraries from environmental samples can provide information about microbial diversity.

As part of the advancement in molecular biology techniques, ribosomal RNA gene sequencing emerged as a versatile approach to study microbes present in environmental samples. The 16S rRNA gene, which codes for the RNA that forms part of the small ribosomal subunit and is important for functional protein formation, is the most used sequencing target for identification of prokaryotic DNA. This gene comprises both highly conserved regions, which allows the development of primers to target a wide array of taxa, but also hypervariable regions that can provide high taxonomic resolution. The extraction of nucleic acids and subsequent amplification is followed by cloning the 16S rRNA genes and sequencing. Cloning of the PCR-amplified sequences allows for accurate species identification. Another common application is the cloning of cDNA for the assessment of gene expression.

PCR-based fingerprinting methods

DNA fingerprinting examines part of the genetic information contained in nucleic acids extracted directly from environmental samples. For decades, various techniques such as denaturing gradient gel electrophoresis (DGGE), temperature gradient gel electrophoresis (TGGE), terminal restriction fragment length polymorphism analysis (T-RFLP), and automated ribosomal

intergenic spacer analysis (ARISA) were developed for DNA fingerprinting microbial communities. DNA extracted from environmental samples comprises fragments from all microbes in the community. Primers targeting the variable regions of the 16S rRNA gene are used in amplification and then gel electrophoresis is used to visualize and differentiate amplified fragments based on their size and sequence variability. These techniques provide rapid, inexpensive information on the community composition profiles and diversity between soil samples without the need to grow microbes on culture media.

Both DGGE and TGGE are based on the differential bond strength between double DNA strands as a function of the proportion and order of DNA bases. Strands richer in guanine-cytosine nucleotide base pairs (GC), or with more collocated GC, are less easily denatured. Differential denaturation can be achieved along a polyacrylamide gel containing an increasing gradient of chemical denaturants (usually urea and formamide; DGGE) or exposed to a temperature gradient (TGGE). As the double-stranded DNA fragments partially denature, their *electrophoretic mobility* is significantly reduced. Unequal denaturation among strands with different genetic codes (different order and abundance of DNA bases) will lead to differences in electrophoretic mobility. This produces different band counts, at different locations in the gel and of variable band intensity corresponding to the relative number of microbial taxa and the relative abundance respectively. Gels can be analyzed with imaging software to determine diversity indices and bands can be excised from the gel and sequenced to identify microbial taxa.

T-RFLP technique involves DNA amplification using a fluorescent-labeled primer, followed by restriction enzyme digestion, and fragment size separation through gel electrophoresis. This is possible using an automated capillary gel electrophoresis in a DNA sequencer platform. The fluorescent labeled fragments travel through the gel at variable, size-dependent speeds, and the fluorescence intensity (or peak size) is read by a detector. An electropherogram is thus produced, which can be analyzed using automated fragment analysis programs such as T-REX which calculate peak sizes (TRF length in base pairs—bp). TRF patterns, such as presence or absence and relative abundance of peaks, can be then analyzed using diversity indices and multivariate statistics.

Unlike DGGE or TGGE and T-RFLP, ARISA targets the internal transcribed spacer (ITS) region between the 16S rRNA gene and the gene coding for the large ribosomal subunit (LSU) or 23S rRNA, using specific primers for PCR amplification. In ARISA, electrophoretic separation of fluorescently labeled PCR products generates a community fingerprint that is detected by a sensitive laser on an automated sequencing system. A variation of this method is the quantitative fingerprinting (“qfingerprinting”), which involves a combination of two methods: community fingerprinting analysis and a dilution endpoint PCR. This is a quantitative version of ARISA, qARISA, which can be used for the quantitative estimation of targeted OTUs from complex communities (Ramette, 2009).

High-throughput techniques for community composition and diversity analyses

High-throughput sequencing (HTS) or next-generation sequencing (NGS) is the broad term used to refer to DNA sequencing methods developed over the last couple decades following the capillary sequencing methods (Sanger sequencing). These technologies enable many processes to take place in parallel, which allows for the sequencing of thousands to millions of molecules simultaneously, thus enabling the sequencing of large genomes in a fast and cost-effective manner, but also sequencing of all the genetic material (metagenome) in a sample (Fig. 1). Because NGS increases sequencing coverage, it offers more detailed estimations of community composition and diversity of the soil microbiome than earlier technologies. Consequently, in a very short time NGS techniques have replaced the construction of traditional clone libraries and fingerprinting techniques, revolutionizing the fields of soil microbiology and microbial ecology. The first NGS technology was pyrosequencing (e.g., platform Roche 454), a sequencing-by-synthesis method based on the detection of DNA polymerase activity (i.e., pyrophosphate release) through the emission of visible light (Ronaghi et al., 1998). Pyrosequencing, now rarely used, was followed by other sequencing-by-synthesis technologies developed by Illumina (e.g., MiSeq and HiSeq) that use dNTPs with fluorescent labels, and which are still highly popular. At around the same time as Illumina, a different type of technology known as Sequencing by Oligonucleotide Ligation and Detection (SOLiD), came to market and is still available today. Ion semiconductor sequencing, or Ion Torrent sequencing, is another available sequencing platform on the market which does not use optics, like pyrosequencing and Illumina, but rather the production of hydrogen ions that are generated during DNA polymerization. In 2022, we are already into the next wave of sequencing technologies called ‘third generation’, which is characterized by increased read length (e.g., Pacific Biosciences, Oxford Nanopore) and portable technologies which can be brought to the field (e.g., Oxford Nanopore MinION sequencer). The performance of these platforms varies in terms of sequence capacity, genome depth, and quality, which are also associated to differences in terms of cost. Because of the large amount of data (i.e., sequences) produced by NGS, several bioinformatics pipelines and tools have been developed that properly process and interpret results. In this section, we address the main NGS approaches used to explore the composition and diversity of soil microbial communities.

Amplicon-based sequencing

Amplicon sequencing involves HTS and the detailed analysis of one particular gene of interest (marker gene) within an environmental sample, in the way that the genetic diversity reflects the phylogenetic and taxonomic diversity of the microbial communities (Fig. 1). Any gene can be selected for amplicon sequencing, but their choice must be based on the taxonomic resolution that is expected. Target genes are used as taxonomic marker genes for different domains or kingdoms. For example, the 16S rRNA gene is used for bacteria and archaea, the 18S rRNA gene and ITS region are used for fungi, and 18S rRNA and the cytochrome *c* oxidase

Fig. 1 Scope and methodology comparison between amplicon and shotgun sequencing approaches. Amplicon sequencing only targets specific regions of the DNA (e.g., a region of the 16S rRNA gene), whereas shotgun sequencing targets all DNA molecules randomly. The main differences are in the steps of library preparation (1), library sequencing (2) and bioinformatics and data analysis (3). For library preparation (1), amplicon sequencing involves PCR amplification to amplify the target gene region and then incorporate the adapters and barcode sequences needed for parallel DNA sequencing from different samples, while random sequencing does not require PCR amplification and DNA samples are directly barcoded together for sequencing. Additionally, the output of these sequencing technologies also differs during and after bioinformatic processing (3). Whereas amplicon sequencing data allows for taxonomic profiling of the microbiota, with precise taxonomic resolution down to the genus level, shotgun sequencing allows a more accurate taxonomic resolution to the species level and, more importantly, it can be used to produce a metabolic profile of the microbiome based on the content of function-coding genes.

subunit I (COI or CO1) gene are often used for other eukaryotes. Nevertheless, in some circumstances, a functional gene involved may be a better option. This is particularly useful to study microbial transformation of interest (e.g., to study nutrient cycling or biodegradation) but also for low abundance microbial groups. For example, the genes *amoA* and *pmoA* are suitable for studying autotrophic ammonia-oxidizing and methane-oxidizing bacteria, respectively, two functions that are highly relevant for nitrogen and methane cycling and carried out by organisms that represent less than 1% of the soil microbial community.

There are two steps to the amplicon sequencing process: library preparation and parallel sequencing of the target amplicon. The library construction involves two steps: (1) a PCR amplification to yield a pool of target sequences (amplicons), and (2) the addition of sequencing adapters, which are small pieces of DNA designed with 3 functional segments: binding site, index (barcode) and primer binding site that interacts with the NGS platform. The barcode allows multiple samples to be sequenced in a single sequencing run (multiplexing), in a way that the sequences can be identified and tracked by samples (demultiplexing). Finally, amplicons are sequenced using various NGS platforms from the different technologies (i.e., Illumina, PacBio, Oxford Nanopore,

etc.). In this sequencing method, similar to the other NGS technologies, it is possible to sequence a single DNA strand (single-end sequencing) or both forward and reverse strands (paired-end sequencing). This advantage is particularly important for Illumina platforms (the most commonly used), which are limited to producing short reads (150–300 bp). Using paired-end sequencing it is possible to target a long fragment (~500 bp) and then merging forward and reverse reads into a single sequence.

Once amplicons are sequenced, they are analyzed using standardized bioinformatic pipelines. These pipelines are computer software that optimizes sequence denoising, screening, and taxonomic annotation based on reference databases (e.g., SILVA, RDP or Greengenes for prokaryotic 16S rRNA sequences, Unite for fungal ITS data, and BOLD for eukaryotic CO1 amplicons).

Metagenomics (shotgun sequencing)

Shotgun metagenome sequencing involves random and parallel sequencing of all the DNA from all organisms within the microbial community in an environmental sample, and simultaneously adding barcode sequences to each fragment enabling sequencing of several samples at once (multiplexing). In this approach, DNA is randomly broken up into numerous small segments, and then sequenced. Because of the overlapping of the short reads amplified, it is possible to assemble it in long-length sequences named contigs (Fig. 1). Due to this characteristic, shotgun sequencing also makes it possible to sequence and assemble the complete genome of a microorganism of interest, either cultured or directly from an environmental sample.

In terms of taxonomic profiling of the microbial communities, shotgun sequencing enables high sequencing coverage of all the DNA sequences in the sample, including rare species that are often undetected by amplicon sequencing. In addition, since multiple reads from several genes are targeted, it allows species-level detection of the community members. The process of sequence cleaning, assembly, and annotation of shotgun metagenomic data is done via computer software. Many programs or pipelines exist for processing shotgun reads, with two of the most used programs in soil science being MG-Rast and the combination DIAMOND-MEGAN. The RefSeq database hosted by the National Center for Biotechnology Information (NCBI) is one of the main reference databases for taxonomic annotation of shotgun sequence data.

Overall, the main difference between amplicon and shotgun sequencing is their scope: amplicon sequencing targets one specific gene, while shotgun sequencing targets all DNA in a sample. Some advantages to using amplicon sequencing over shotgun sequencing are the smaller cost and that it provides greater coverage for the gene of interest avoiding contamination from non-target DNA. On the other hand, shotgun sequencing has greater scope (DNA from all the domains present in the sample), enabling both taxonomic and functional annotation and profiling of soil microbiome, and provides greater coverage and resolution of the composition of microbial communities.

Single-cell sequencing

Single-cell sequencing (SCS) is HTS sequencing of whole genomes of individual cells in a sample. The process of single-cell sequencing begins with the isolation of an individual cell from its environment, which can be accomplished using a variety of methods such as fluorescence-activated sorting, patch pipettes, and microfluidics techniques. Once cells are isolated, their total DNA is extracted, followed by library preparation and DNA sequencing using NGS techniques. The general functions of SCS include observing genomic heterogeneity between cells within a population and evolutionary relationships between organisms. Applications of SCS specific to soil science include studying rare or unculturable microorganisms, elucidating microbial niches, and studying horizontal gene transfer within a microbial population (Kvist et al., 2007; Walker and Parkhill, 2008).

Concluding remarks

Culture-independent approaches have revolutionized our understanding of soil microbial communities, providing a more comprehensive view of their composition, diversity, and functional potential. These methods have enabled the detection and identification of microorganisms that cannot be cultivated in the lab, offering a more accurate picture of the microbial communities present in soil ecosystems. Despite the advantages of culture-independent approaches, it is important to acknowledge their limitations (e.g., potential biases and limitations in detecting low-abundance microorganisms) when designing studies and interpreting results. Ultimately, the choice of a particular culture-independent approach will depend on the research question, experimental setup, and resource availability. Overall, culture-independent methods represent a powerful tool for studying soil microbial communities and will continue to shape our understanding of microbial ecology and ecosystem functioning in the future.

Abstract

Microorganisms have numerous functions in soils. They are key drivers of soil biogeochemical cycling, which determines the fate of nutrients and organic matter. This gives microbial activity a key role in soil ecosystem services such as plant growth, carbon sequestration and regulation of greenhouse gas emissions. Since the beginnings of microbial ecology, technological advancements have increased our understanding soil microbial communities and shed light on the “black box” of microbial activity. This chapter revisits the most influential techniques and methodologies that have helped us study microbial function in soil.

Glossary

Amplicon sequencing DNA or RNA sequencing technique that analyzes a specific region of the genome previously targeted and amplified using PCR.

Biochemical techniques Techniques developed in the mid to late 20th century to measure biochemical reactions carried out by active microbial cells or their extracellular enzymes.

Biodegradation Process of breaking down complex substrates into simpler components.

Biomagnification Process by which the concentration of a substance increases in the tissues of organisms at higher trophic levels.

Black box measurements Techniques that quantify substrates and products without exact knowledge of the reactions or organisms involved.

Catabolic capacity Capacity of a microorganism or microbial community to metabolize a given substrate.

Community-level physiological profiling (CLPP) A rapid method to assess the metabolic potential of a microbial community by simultaneously testing their growth with different carbon sources.

Isotope Variations of a chemical element differing in its number of neutrons and thus atomic mass.

Isotopic fractionation Preferential depletion or enrichment of one isotope in comparison to the others, leading to changes in isotopic proportions.

Isotopic labeling Process of marking specific substrates with a stable or radioactive isotope to trace their fate and transformations.

Machine learning algorithms Algorithms that can learn from and make predictions on data, using statistical models to recognize patterns and relationships.

Net activity rates Activity rates that represent the balance between production and consumption of reaction products.

Next-generation sequencing (NGS) Also known as second-generation sequencing, this term that comprises all high-throughput technologies for massively parallel sequencing of DNA or RNA.

Omics Any of several areas or disciplines in biology defined by the characterization or quantification of a specific type of biomolecule or the totality of a molecular process within an organism (e.g., genomics, transcriptomics, proteomics).

Radioisotope Radioactive isotopes, meaning they decay over time, emitting ionizing radiation until reaching a stable state.

Radiotracer Compound that has been labeled with a radioactive isotope of an element.

Stable isotope probing (SIP) Technique based on the labeling of substrates with a stable isotope followed by the quantification of a specific microbial biomarker (e.g., DNA).

Stable isotope Isotope that is non-radioactive, which means it does not decay over time or emit ionizing radiation.

Trophic level Position of an organism in a food chain, determined by the number of steps it is away from the primary producers.

- Omics techniques for functions analysis

Introduction

The soil microbiota plays a major role in ecosystem functioning. In general terms, microbial communities are not only abundant and genetically diverse, but also have ample metabolic capacity and versatility. Hence, microbes are the main drivers of soil biogeochemical cycling, with consequent effects on the fate of nutrients and organic matter, as well as the degradation of xenobiotics or contaminants. This makes microbial activity key to plant nutrition and fitness, carbon sequestration and regulation of greenhouse gas emissions, among other ecosystem services provided by soils. Some soil microorganisms can also interact directly, and sometimes symbiotically, with plants and animals, either promoting their growth or acting as pathogens. The success of each interaction depends on many factors, including the influence of other microbes in the community (e.g., competition which leads to disease suppression). In addition, soil microorganisms are intimately associated with the soil mineral and organic phases, and can influence the soil environment (e.g., through particle aggregation, and contributing to the dynamics of water, and air).

Due to the key roles of the soil microbiota in soil functioning, as well as its sensitivity to environmental changes (e.g., resulting from anthropogenic activities), the study of microbial functions in soil has become of great interest in soil science. The study of microbial ecology, including microbial activity, began during the 19th century. Since then, more and increasingly sophisticated tools have allowed us to shed light on what is known as the “black box” of microbial activity. This chapter revisits the most influential techniques and methodologies that have helped the understanding of microbial functions in soil. These techniques are organized in terms of their application to soil sciences (i.e., the activity or function being measured).

Traditional techniques to study microbial function in soil

This section includes techniques that were developed in the mid to late 20th century to measure biochemical reactions carried out by active microbial cells or their extracellular enzymes (hence the name “biochemical techniques”). These techniques have been key

to the study of biogeochemical cycling of elements in soil and are among the first ones to describe soil microbial communities without relying on isolation and culturing, which can only recover a small fraction of the microorganisms present in soil.

Many of the techniques described in this section are “black box” measurements, meaning that substrates and products are quantified without exact knowledge of the reactions or organisms involved. These techniques usually estimate the activity carried out by a wide array of organisms and enzymes and are therefore representative of the whole microbial community. Measurements may target general parameters (e.g., respiration, N mineralization), that characterize the overall microbial activity and are directly related to microbial biomass. Other, “specific” techniques, measure the activity of hydrolytic enzymes, which can be extracellular (exoenzymes) and are not necessarily associated with overall microbial biomass and activity. Often, measurements represent net activity rates, as products of the measured reaction may be consumed or transformed in subsequent reactions. Although all methods described here can be carried out in laboratory incubations (*in vitro*), some can be adapted to measure microbial activity under field conditions (*in situ*). *In vitro* techniques have the obvious advantage of allowing control of the incubation conditions. *In situ* methods reflect real conditions more accurately and can facilitate the incorporation of spatial and temporal variability of these functional measurements.

Despite the great technological advancements of recent years, including the development of functional omics techniques, these traditional approaches are still widely used. This is partly due to their small cost, simplicity, and accessibility, but also because they still constitute the most straightforward way to measure microbial and enzymatic activity in soil. Additionally, many of them already have internationally standardized protocols that facilitate comparisons across research laboratories.

Microbial respiration

Methods for determining soil microbial respiration are among the oldest and most commonly used to measure the global metabolic activity of microbial communities. These assays measure the oxidation of organic matter by aerobic heterotrophic microorganisms without supplementation of organic carbon substrates (i.e., basal respiration). Aerobic respiration uses oxygen (O_2) as an electron acceptor and generates CO_2 and water as end products. Both O_2 consumption and CO_2 production can be measured to estimate soil microbial respiration, but the latter is more sensitive due to the smaller concentration of CO_2 in the atmosphere. *In vitro* methods can be either static (i.e., a closed incubation system) or dynamic (i.e., continuous aeration with CO_2 -free air). In addition, CO_2 measurements can be taken once, after a set period of time (~24–72 h), or several times during a single incubation. For longer incubations (e.g., weeks or months), measurements are carried out at regular intervals or continuously (e.g., with respirometers or gas flux chambers). Emitted CO_2 can be captured in an alkali trap (NaOH) followed by chemical titration or electrical conductivity measurements (electro titration), or by measuring the headspace CO_2 concentration using gas chromatography or infrared gas analyzers. A commonly used static approach combines the incubation of soil samples with NaOH traps in air-tight containers, followed by precipitation with $BaCl_2$ or $SrCl_2$ and titration with acid. For *in vitro* approaches, incubations are conducted under optimized temperature and moisture conditions. Alternatively, the quick CO_2 -Burst or 24 h evolved CO_2 assay uses thin-layer gel chromatography and a pH-sensitive gel to provide a colorimetric measure of the respiratory response. *In vitro* basal respiration can be used to compare the general activity of different soils, although it is also highly correlated with the availability of mineralizable C. For that reason, some protocols recommend the pre-incubation of samples for 7–10 days before carrying out the assays. In addition to general microbial activity, information about ecosystem maturity or disturbance level can be obtained from the metabolic quotient (qCO_2), calculated as the ratio of microbial respiration to biomass. Standardized protocols for soil respiration measurements are available in ISO 16072:2002 and ISO 17155:2012. Field methods are also available to measure soil respiration at the ecosystem level, but these will measure net ecosystem exchange of CO_2 , including the respiration of all present organisms, minus the CO_2 used in photosynthesis, when applicable. Some field methodologies include static or dynamic chambers, solid-state infrared gas analyzer (IRGA) probes buried in soil, and eddy covariance.

Catabolic capacity and biodegradation

Different methodologies are available to assess the metabolic response of soil microbial communities to the incorporation of an organic carbon substrate. These may employ simple substrates (e.g., sugars, amino acids, organic acids), or evaluate the degradation of complex substrates (e.g., plant litter). While the simple-substrate methods have been primarily used to assess catabolic capacity or diversity, the latter focus on the capacity of a soil community to degrade a complex substrate of interest.

Simple substrate utilization assays

Substrate-induced respiration (SIR) is known for its utility as a microbial biomass measurement. However, the respiratory response of a microbial community to the addition of a simple substrate can provide information on the capacity of the community to metabolize a given substrate. Additionally, evaluating the respiratory response of microbes to the addition of a range of carbon substrates (i.e., carbon source utilization patterns) can be useful to estimate the catabolic capacity or diversity of a community. All these methods measure potential activity levels under optimized incubation conditions and non-limiting substrate concentrations. A simple way to carry out this analysis is to run multiple SIR assays in parallel (*multi-SIR*), by amending soil with different C substrates, incubating the resulting soil slurries for a pre-determined amount of time and measuring CO_2 in the headspace (Degens and Harris, 1997). Less labor-intensive methods are the high-throughput techniques that use different types of microtiter plates (microplates). These methods are known widely as community-level physiological profiling (CLPP), although

the term is sometimes used to refer exclusively to one specific methodology using Biolog™ plates or similar approaches (Garland and Mills, 1991). *Biolog-CLPP* is carried out in soil suspensions amended with different carbon sources and with a redox indicator dye to detect the production of CO₂. These plates can then be analyzed in a microplate reader or spectrophotometer. For that reason, the method is considered culture-dependent, which is prone to selective enrichment, meaning that it is more likely to detect fast-growing organisms (e.g., bacteria). A fluorescence-based method carried out in a BD Oxygen Biosensor system (*BDOxy-CLPP*) solved some of these limitations, although its use was never as widespread (Garland et al., 2003). *BDOxy-CLPP* improves sensitivity and enables testing of lower substrate concentrations compared to other methods (multi-SIR, *Biolog-CLPP*, *MicroResp*™), by measuring the depletion of oxygen, which is less soluble in water. Furthermore, in comparison to *Biolog*, *BDOxy-CLPP* allows testing of soil suspensions that are more turbid, and even of intact soil “microbags” by using a fluorophore located at the bottom of the wells. In contrast, a different method called microrespirometry or *MicroResp* works directly on soil samples (i.e., culture-independent) (Campbell et al., 2003). With *MicroResp*, the amended samples are in a deep-well microplate, while a smaller microplate on top of it has the detection gel with the redox indicator dye, where it is sealed in a way that each sample well is only connected to one detector well. This top microplate can be read with the same microplate readers used for *Biolog-CLPP*. Even though *MicroResp* also requires relatively large substrate concentrations, it can be coupled with ¹⁴C-labeled substrates to work at smaller concentrations.

Complex substrate biodegradation assays

Biodegradation assays can be used to measure the degradation or decay rate of complex substrates (e.g., plant biomass, cellulose, lignin, pollutants, xenobiotics) to simpler intermediates or end products. Degradation of these complex substrates can be carried out in one or several steps by living cells or extracellular enzymes. Thus, measurements can reflect the activity of a single microbial species, a group of microbes, or the presence of extracellular enzymes capable of degrading the added substrate or its intermediates. Commonly, methods involve the addition of a specific substrate to a soil sample to then measure the rate of decomposition as weight loss or change in substrate or product concentration. A common procedure to evaluate plant biomass decomposition is the *litterbag* method (Schinner, 1996). Plant litter is weighed into nylon mesh bags that can be positioned on or below the soil surface (sometimes stratified, at different depths). The mesh allows air, water and nutrients to be exchanged freely with the surrounding soil, and different mesh sizes can be used to include or exclude different organisms (e.g., fauna). After days or months the residual weight of dried litter is measured and a linear decomposition rate is calculated from the difference relative to the initial dry weight. Changes in chemical composition can be also assessed using the same litter. In biodegradation assays, including *litterbag*, substrates can be labeled with radioactive or stable isotopes. These assays can be carried out under optimized conditions (*in vitro*, microcosms or mesocosms) or in the field.

Microbial nitrogen transformations

Biochemical methods to study microbial N transformations are available for four major steps of N cycling: ammonification, nitrification, denitrification and N₂ fixation.

Nitrogen mineralization and nitrification

Generally speaking, N mineralization is understood as the conversion of organic to inorganic N and it starts with the depolymerization, or aminization, of large N-containing compounds (e.g., proteins) to N-containing monomers (e.g., amino acids, nucleic acids). Then, heterotrophic microorganisms hydrolyze those simpler organic N compounds to ammonia (NH₃) in a process known as ammonification. As ammonia can be rapidly oxidized to nitrate in a two-step process known as nitrification these processes are commonly analyzed together. Autotrophic nitrification occurs in two steps: the oxidation of ammonia to nitrite (NO₂⁻) by particular bacterial and archaeal species, followed by the oxidation of nitrite to nitrate (NO₃⁻) by some bacteria. Under certain conditions, heterotrophic nitrification can be carried out by bacteria and fungi. Soil N mineralization is generally quantified as the production of mineral N (ammonia and nitrate). Nitrite is not usually measured because its concentration in soils is very small. One type of *in vitro* testing involves incubations under aerobic conditions with optimized temperature and moisture levels, followed by mineral N extraction and quantification. In incubation-leaching methods, soil samples, with or without organic amendments, are incubated in a column and leached mineral N is regularly determined. Some techniques exclusively quantify *ammonification*, which is usually the rate limiting step of N mineralization. This is conducted by incubating samples under waterlogged conditions and quantifying the production of ammonia (Kandeler, 1996). Anaerobic conditions inhibit nitrification and may also reduce immobilization and protease activity. Methods that quantify ammonification can also be used to estimate mineralizable N, as the substrate is limiting, or it can be carried out with amendments such as arginine (i.e., arginine ammonification method). Alternatively, potential *nitrification* can be measured by incubating samples with ammonium amendments. Field measurements of soil N mineralization usually require working with buried samples in columns (undisturbed) or buried bags (disturbed), with ammonium and nitrate content being determined by laboratory analysis. Ion-exchange resins can be applied to the bottom of columns to account for leaching losses, and at the top to account for deposition (atmospheric, run-off). Depending on the protocol, mineral N can be quantified via spectrophotometry, acid titration or using an automated analyzer. All these assays measure net N mineralization, as some ammonia and nitrate will be immobilized or transformed via other reactions. Gross mineralization can be estimated using labeled substrates. Standardized protocols for N mineralization are available in ISO 14238:2012.

Denitrification

Denitrification is the reduction of nitrate to nitrogen gases, primarily nitrous oxide (N_2O) and dinitrogen (N_2). In this stepwise process, nitrate (NO_3^-), nitrite (NO_2^-), nitric oxide (NO) and N_2O can act as electron acceptors in anaerobic respiration. Although, this process is not restricted to exclusively anaerobic soils, and can occur in hotspots or microsites where O_2 is limiting. Depending on the organism and the environmental conditions, denitrification can be complete (N_2 as product) or incomplete (N_2O or NO as products). Denitrification can be carried out only by active microbial cells, mostly heterotrophic prokaryotes but also, as found more recently, by some fungi and autotrophic bacteria (i.e., nitrifier denitrification). The most common method to measure denitrification is through the *acetylene-inhibition technique* (AIT) (Alef, 1995b). In AIT, the N_2O -reductase enzyme is inhibited by acetylene and the released N_2O , equivalent to losses as both N_2O and N_2 , is measured using gas chromatography. Incubations are carried out in air-tight containers under optimized temperature and moisture conditions for between 48 h (actual rates) and 200 h (potential rates), in sieved soil samples or undisturbed soil cores. Potential denitrification activity can also be measured when adding nitrate as a substrate. A variant of the AIT, known as the soil cover method, allows the making of this estimation in situ, under field conditions. There are also several strategies to distinguish autotrophic from heterotrophic denitrification, for example, using inhibitors, ^{15}N labeling, or different acetylene concentrations. ^{15}N -labeled substrates can also allow gross denitrification rates to be measured, as opposed to net denitrification rates. Standardized protocols are available in ISO 20131-1:2018 and 20131-2:2018.

Nitrogen fixation

The reduction of atmospheric dinitrogen (N_2) to ammonia (NH_3) by nitrogenases is commonly known as N_2 fixation or biological N fixation. This process is exclusively carried out by prokaryotes both symbiotically and non-symbiotically (i.e., free-living). The most popular method to quantify this process is via the *acetylene reduction method*. Acetylene can be reduced by the nitrogenase enzyme complex, yielding ethylene as a product. The assay consists of the incubation of soil samples in airtight containers with an atmosphere enriched in acetylene, under optimized temperature and moisture conditions. The ethylene produced can be measured in gas samples using gas chromatography. Fixed-N can be obtained using a conversion factor obtained with $^{15}\text{N}_2$ assays. For accurate results, it is recommended that the proportion of ethylene produced by microbes via other processes is extracted and quantified (e.g., inhibiting acetylene reduction by nitrogenases with carbon monoxide). The acetylene reduction method can be complemented with glucose amendments. This assay has been carried out on intact soil cores, sieved soil samples, or in situ. Actual N fixation rates can be obtained by using dinitrogen labeled with the stable isotope ^{15}N (see below). No standardized protocols are available.

Enzymatic activity

Hydrolytic enzymes break macromolecules down to smaller molecules (e.g., cellulose to sugars, proteins to amino acids). This can take place intracellularly or attached to active cells, intracellularly in dead or dormant cells, or extracellularly (e.g., adsorbed to soil colloids). While most of the extracellular enzymes are of microbial origin, the measured activities are not necessarily associated with active microorganisms because active enzymes can be stabilized on soil colloids. Most common methods are based on the use of defined substrates (mostly synthetic) with the measurement of the reaction product carried out under optimized conditions (e.g., temperature, pH, incubation time). This means the data generated by these methods describe potential enzymatic activities and not actual activity rates. These accessible tools to measure soil enzymatic activity became available in the 1960s–70s and have been widely used ever since. Enzymatic methods commonly used *in vitro* are listed in Table 1.

Dehydrogenase activity

Dehydrogenases are intracellular enzymes that catalyze oxidation-reduction reactions in the electron transport chain during the aerobic oxidation of organic substances. Consequently, measurements of dehydrogenase activity represent total oxidative activity of aerobic heterotrophic microorganisms and can be used as a measurement for general microbial activity. The assay is based on the use of synthetic electron acceptors instead of O_2 : 2,3,5-triphenyltetrazolium chloride (TTC) or 2-(4-iodophenyl)-3-(4-nitrophenyl)-5-phenyltetrazolium chloride (INT) (see Table 1). The products of these reactions, triphenyl formazan (TPF) and idonitrotetrazolium chloride (INF), respectively, can be measured by spectrophotometry.

Hydrolysis of fluorescein diacetate

Fluorescein derivatives such as fluorescein diacetate or 3,6-diacetyl-fluorescein (FDA) can be hydrolyzed by extracellular and membrane-bound lipases, esterases and proteases (Table 1). These non-specific hydrolases are produced by a wide range of microorganisms, which is why the hydrolysis of FDA is considered an estimator for global hydrolytic activity. This method consists of incubating soil samples with FDA under optimized temperature and pH, extracting the produced fluorescein and quantifying it via spectrophotometry. Standardized methods are available in ISO 23753-1:2019 and 23753-2:2019.

Table 1 Most commonly used assays of soil enzymatic activity

Enzyme or process	Enzyme Commission Number (EC) ^a	Reaction/s targeted	Original publication/s	Available protocols
General activity				
Dehydrogenase	1.1.1.	Oxidation of OM by several oxidoreductases. Used as measurement of overall microbial activity.	Lenhard (1956), Thalmann (1968), von Mersi and Schinner (1991)	Schinner et al. (1996), Bloem et al. (2006), Alef and Nannipieri (1995) ISO 23753:2019
Hydrolysis of fluorescein diacetate		Global hydrolytic activity (lipases, esterases and proteases).	Adam and Duncan (2001)	Bloem et al. (2006), Alef and Nannipieri (1995)
C-cycling enzymes				
Cellulases	3.2.1.4,	Cleavage of cellulooligosaccharides from non-reducing ends (exo), cleavage of glucosidic linkages (endo)	Hope and Burns (1987), Schinner and von Mersi (1990)	Schinner et al. (1996), Alef and Nannipieri (1995)
(endoglucanase + exoglucanase + β -2 β -glucosidase (aka cellobiase)	3.2.1.91, 3.2.1.21			
Saccharase (aka invertase)	3.2.1.26	Hydrolysis of sucrose to fructose and glucose	Hoffman and Dedeken (1965), Eivazi and Tabatabai (1988) Schinner and von Mersi (1990), Hoffman and Pallauf (1965)	Schinner et al. (1996), Alef and Nannipieri (1995)
Xylanase	3.2.1.8	Hydrolysis of xylans to oligosaccharides (<i>endo</i> -) and oligosaccharides to monomers (<i>exo</i> -)	Schinner and von Mersi (1990)	Schinner et al. (1996), Alef and Nannipieri (1995)
P-cycling enzymes				
Phosphomonoesterases (phosphoric monoester hydrolases)	3.1.3.-	Hydrolysis of organic phosphomonoesters to phosphate	Tabatabai and Bremner (1969), Eivazi and Tabatabai (1977)	Schinner et al. (1996), Alef and Nannipieri (1995) ISO 20130:2018
Phosphodiesterase (phosphoric diester hydrolases)	3.1.4.-	Hydrolysis of organic phosphodiester to phosphomonoesters	Eivazi and Tabatabai (1977), Browman and Tabatabai (1978)	Schinner et al. (1996), Alef and Nannipieri (1995)
N-cycling enzymes				
Proteases	3.4.21.-	Proteins to polypeptides, oligopeptides to amino acids	Hoffmann and Teicher (1957), Ladd and Butler (1972)	Schinner et al. (1996), Alef and Nannipieri (1995)
Amidase	3.5.1.4	Hydrolysis of amides to ammonia and carboxylic acid	Frankenberger and Tabatabai (1980)	Alef and Nannipieri (1995)
Urease	3.5.1.5	Hydrolysis of urea to ammonia and carbon dioxide	Tabatabai and Bremner (1972), Kandeler and Gerber (1988)	Schinner et al. (1996), Alef and Nannipieri (1995)
Nitrate reductase	1.7.99.4	Dissimilatory reduction of nitrate to nitrite (anaerobic conditions)	Abdelmagid and Tabatabai (1987)	Schinner et al. (1996)
Arylamidase	3.4.11.2	Hydrolysis of N-terminal amino acid from peptides, amides or arylamides	Acosta-Martínez and Tabatabai (2000)	
S-cycling enzymes				
Arylsulfatase	3.1.6.1	Hydrolysis of aryl sulfates (organic aromatic sulfate esters) to sulfate.	Tabatabai and Bremner (1970)	Schinner et al. (1996), Alef and Nannipieri (1995)

Specific enzymatic activities

Other intra- but mostly extracellular hydrolases are involved in phosphorus, nitrogen, sulfur and carbon cycling. Related assays commonly employ substrates that change color or gain fluorescence as products of the enzymatic activities accumulate to then be assessed spectrophotometrically or fluorometrically (see Table 1). Conversely, quantification of substrate depletion, rather than production can be measured but these assays are less common. Many colorimetric methods use synthetic substrate analogs such as conjugates of *p*-nitrophenol. Fluorometric methods are more sensitive as they use an artificial fluorescent molecule bound to one or more natural molecules. Fluorogenic substrates are conjugates of 4-methylumbelliferone (MUB) and 7-amino-4-methyl coumarin (AMC). Bench-scale and high-throughput microplate methods are available for both colorimetric and fluorometric approaches. Standardized protocols for high-throughput colorimetric analysis of several hydrolases (e.g., arylamidase, arylsulfatase, β -galactosidase, α -glucosidase, β -glucosidase, *N*-acetyl-glucosaminidase, phosphatases and urease) can be found in ISO 20130:2018.

Isotopic techniques to study microbial function in soil

Isotopes are variations of the same chemical element differing in their number of neutrons and thus mass. Stable isotopes are non-radioactive (i.e., they do not decay over time or emit ionizing radiation), which makes them safer to manipulate than radioactive isotopes also known as radioisotopes. In contrast, radioisotopes decay over time, emitting ionizing radiation until reaching a stable state. Labeling specific substrates with a stable or radioactive isotope makes it possible to trace their fate and utilization by soil microorganisms and through the soil food web. Isotopic labeling addresses some of the limitations imposed by the traditional techniques described earlier. For example, it allows calculation of gross transformation rates and substrate residence times. Some of these techniques (e.g., stable isotope probing) assist with the elucidation of “black box” microbial activity mentioned earlier, by detecting which organisms are using the compound of interest. An additional application of stable isotopes in microbial ecology is to study the natural isotopic signature of compounds and their isotopic fractionation.

Stable isotopes techniques

There are two main approaches to working with stable isotopes. The first is based on their natural abundance and fractionation, while the other consists of enriching a sample with a particular stable isotope to study its transformation or use by specific microbial groups. The most studied stable isotopes in soil microbial ecology are C and N, and to a lesser extent S and O. All these elements exist in nature mostly in one form (^{12}C , ^{14}N , ^{32}S and ^{16}O), but they also have less abundant stable isotopes that are useful to study their dynamics in nature (^{13}C , ^{15}N , ^{34}S and ^{18}O). Because phosphorus only has one stable isotope (^{31}P), no stable isotope techniques are available for it. These elements also have the advantage of being relatively light, which enhances differences in isotopic fractionation, in addition to being relevant to many biological processes. The isotope ratio (δ , in in parts per thousand (‰) relative to a standard) is generally quantified by converting the compounds to simple gases (e.g., CO_2 , SO_2 , N_2) followed by isotope ratio mass spectrometry (IRMS).

Natural abundance and isotopic fractionation

In nature, preferential depletion or enrichment of one isotope in comparison to the others leads to changes in isotopic proportions. This process is known as isotopic fractionation and can be used to measure changes in the isotope ratio (δ), which represents the abundance of an isotope relative to an international standard (‰) (e.g., $\delta^{13}\text{C}$, $\delta^{34}\text{S}$, $\delta^{15}\text{N}$). In biological reactions, it is thermodynamically more favorable to use lighter isotopes over heavier isotopes and, therefore, lighter isotopes are usually enriched in the product of a reaction compared to the substrate. Isotopic fractionation can thus be a useful method to identify if a reaction was carried out by microorganisms or not. Isotopic composition, in particular ^{13}C and ^{15}N enrichment, can allow the elucidation of trophic levels of soil organisms, as higher trophic levels are more enriched in heavier isotopes than lower levels. This occurs because heavier isotopes are more selectively incorporated into the tissues of these organisms and then concentrated due to the process of biomagnification. Lighter isotopes, on the other hand, are predominantly lost as they preferentially participate in biochemical processes that transform them into lighter molecules more easily lost or respired. Another widespread approach using stable isotopes makes use of the different natural ^{13}C abundance or ^{13}C to ^{12}C ratio of C_3 and C_4 plants (–40‰ to –20‰ vs. –17‰ to –9‰, respectively) to evaluate decomposition and fate of plant inputs. The isotopic signature of each vegetation remains in soil organic matter even if microbial transformations cause some fractionation.

Isotopic enrichment

Artificially enriching substrates with stable isotope tracers to track their fate makes them useful to estimate gross, as opposed to net, microbial transformation rates. Since these methods require the labeling of a specific compound, they are less suitable to analyze general microbial activities. In C cycling studies, labeling can be done by enriching simple substrates (e.g., glucose, herbicides) or more complex substrates (e.g., plant residues) with ^{13}C (Gerzabek et al., 1996). In plant-soil systems, pulse labeling of plants with $^{13}\text{CO}_2$ has been applied to study the final fate of plant-derived C in soils. Tracing experiments with the stable isotope ^{15}N has improved our understanding of several N-cycling processes in soil (Brumme and Aden, 1995). For example, ^{15}N -labeled fertilizers, or litter of plants grown with such fertilizer, can be used to track their final fate in soils or plants. Likewise, denitrification losses can be estimated after applying ^{15}N -fertilizer to soils and measuring labeled denitrification products ($^{15}\text{N}_2$ and $^{15}\text{N}_2\text{O}$). Gross N nitrification or N mineralization rates can be assessed using an isotopic dilution technique. Here, the soil nitrate or ammonium pools are labeled and the abundance and isotopic ratio of the pool is measured as it is diluted by unlabeled N from mineralization and nitrification. Isotopic enrichment experiments have also been used to measure rates of heterotrophic and autotrophic nitrification, separately. Another common application of the isotope ^{15}N is to estimate biological N_2 fixation. While the use of ^{15}N has been carried out more frequently in plants, it has also been used to estimate the amount of N derived from symbiotic associations with diazotrophic bacteria. To estimate N_2 -fixation in soil samples, samples are incubated in an atmosphere containing $^{15}\text{N}_2$, and then the ratio of ^{14}N to ^{15}N in the soil is measured. The isotope ^{18}O has also been applied in soil microbiology and biochemistry, for example, to study P cycling using $\text{P}^{18}\text{O}_2^{4-}$ or microbial growth and degradation using H_2^{18}O (Tamburini et al., 2012; Zhran et al., 2021).

Stable isotope probing

Stable isotope probing (SIP) is based on the labeling of substrates with a stable isotope followed by the quantification of microbial biomarkers, such as phospholipid fatty acids (PLFA), DNA, RNA or proteins (Radajewski et al., 2000). Labeling commonly involves ^{13}C , although ^{15}N and ^{18}O have also been used. Substrates are usually chosen based on the microbial group of interest (e.g., to target a specific functional group). Once the labeled substrate is applied to the soil sample and incubated, microbial communities can be studied by extracting the biomarker or cellular component (e.g., DNA), separating lighter and heavier fractions using density-gradient centrifugation, and analyzing those fractions as needed (e.g., DNA sequencing) (Fig. 1). By integrating the use of specific substrates with the identification of microbes capable of utilizing them, SIP constitutes a useful tool to link structural and functional aspects of soil microbial communities. A common application of SIP is to evaluate the use and incorporation of a labeled substrate by different microbial groups within a complex community.

Radioisotope techniques

Radiotracer techniques

Radiotracers are compounds that have been labeled with a radioactive isotope of an element. The presence of the radiotracer in different pools or fractions can be detected by measuring radioactivity, usually by liquid scintillation counting. Like stable isotope techniques, these methods track the fate of a specific compound and calculate gross turnover rates. Additionally, the greater sensitivity of radiotracer methods allows detection of smaller substrate concentrations that are more representative of real conditions in soil. However, radiotracer techniques are more useful for focusing on the transformation of a specific compound, than to measure general activity. The radioisotopes most used in soil microbial ecology are ^{14}C , ^{35}S , ^{32}P and ^{33}P , with half-lives long enough to allow for accurate quantification. The most restrictive half-life is from ^{32}P (~14 days), followed by ^{33}P (~24 days) and ^{35}S (~88 days), while ^{14}C has a half-life of around 5000 years. There are no long-lived radioisotopes of nitrogen and oxygen, which is why radiotracer techniques for these two atoms are not widespread. The radioisotope ^{14}C can be used to label substrates (e.g., glucose, cellulose, plant residues, pesticides) and track their use by soil microorganisms (Alef, 1995a). For example, an organic substrate labeled with ^{14}C is added to the soil and the evolved $^{14}\text{CO}_2$ from respiration is measured. The stable isotope ^{13}C is also available for pulse labeling of plants with $^{13}\text{CO}_2$, which facilitates tracking the use of plant-derived C compounds by the soil biota. Moreover, isotopic dilution techniques are available to measure gross nutrient transformation rates in soil. For example, ^{35}S has been applied to study the use and transformation of sulfur compounds in soil, including: immobilization and mineralization and plant uptake of sulfate ($^{35}\text{SO}_4^{2-}$), reduction to hydrogen sulfide (H_2^{35}S) by sulfate-reducing bacteria during anaerobic respiration (e.g., in flooded soils), and oxidation of elemental sulfur ($^{35}\text{S}^0$) (McLaren et al., 1985). Radiotracer techniques for phosphorus

Fig. 1 Schematic overview of stable isotope probing for nucleic acid analyses. This analysis is frequently carried out on environmental samples such as soil ①, which are incubated with a ^{13}C - or ^{15}N -labeled substrate ②. Following incubation, DNA or RNA is extracted from the samples ③ and the heavier labeled nucleic acids from the organisms who assimilated the labeled substrate are separated from the lighter unlabeled fraction using density gradient centrifugation ④. Both fractions are then recovered and used for downstream analysis (e.g., sequencing) ⑤ and ⑥. The flow at the top represents a control with unlabeled substrate which is carried out in parallel. Created with Bio Render (<https://biorender.com/>).

usually involve labeling phosphate fertilizers ($^{32}\text{PO}_4^{2-}$ or $^{33}\text{PO}_4^{2-}$) to study P transformations in plant-soil systems such as immobilization, mineralization, movement and plant or mycorrhizal uptake (Harrison, 1982; Zapata and Axmann, 1995). Radiotracer techniques can be carried out in laboratory incubations, microcosms, and field studies.

Thymidine and leucine incorporation

Incorporation of thymidine, labeled with the radioisotope ^3H ($[^3\text{H}]$ thymidine), or ^{14}C -labeled leucine ($[^{14}\text{C}]$ leucine), has been used to estimate gross bacterial growth rate in soils (Bloem and Bolhuis, 2006). Since thymidine is a precursor of the DNA nucleotide base thymine, its incorporation gives information about DNA synthesis. On the other hand, leucine is an amino acid and its incorporation is indicative of protein synthesis. These methods are more suitable indicators of bacterial growth, rather than simply measuring biomass, because they assess gains and losses (e.g., death or predation). Although these isotope methods were developed independently, when carried out simultaneously they lead to greater accuracy, as they both have different advantages and limitations. For example, thymidine is only incorporated by bacteria, although it excludes some groups, whereas leucine can be incorporated by bacteria but also other microbial groups.

Omics techniques to study microbial function in soil

Despite the major role that soil microorganisms play in soil and ecosystem functioning, understanding the functioning of complex soil microbial communities is still a major challenge owing to the high proportion of non-culturable taxa. In recent decades, the advancement of next-generation sequencing (NGS) technologies led to the emergence of new scientific disciplines known as omics such as metagenomics, metatranscriptomics, metaproteomics and metabolomics. Omics techniques enable the analysis of the functional traits of microbial communities in soil. Omics are defined as high-throughput biochemical assays that comprehensively and simultaneously measure molecules of the same type from a biological sample. These omics approaches delve into the different processes of DNA-to-protein translation, as well as protein and metabolite production (Fig. 2), which is caused by the functioning of the microbial community in different contexts (e.g., bulk soil, rhizosphere, wetlands). As such, omics techniques and their integration are promising tools to illuminate the relationship between structure and function in complex microbial communities.

Sequence-based metagenomics

Whereas metagenomics is the study of all genetic material from a mixed community of organisms that are recovered directly from the environment, sequence-based functional metagenomics refers to the analysis of metagenomic data focusing on the abundance of gene families, pathways and systems, instead of the taxonomy. These analyses facilitate studying the functional capabilities of soil communities in different contexts (e.g., environmental conditions, treatments). For metagenomic functional profile analyses, one of the most used approaches is the DIAMOND + MEGAN pipeline. DIAMOND is a high-throughput DNA-to-protein alignment tool that rapidly aligns translated DNA sequences against a reference database of protein sequences such as the Kyoto Encyclopedia of Genes and Genomes (KEGG) database. The output of DIAMOND is then processed using MEGAN, which is a highly efficient software for interactive analysis of the functional gene content of the microbiomes from hundreds of samples. MEGAN supports the use of metadata and provides several databases for functional profiling such as SEED, eggNOG, KEGG and InterPro2GO (Huson et al., 2016). The selection of a database for annotation of functional genes depends on the type of samples under analysis (i.e., according to similar studies on the subject). All these databases are up-to-date and mostly share similar annotations, but their individual characteristics may be critical for certain data under study. For instance, Clusters of Orthologous Genes (COG) only includes information about bacteria and archaea, while EuKaryotic Orthologous Groups (KOG) is a eukaryote-specific version of the COG, and eggNOG (evolutionary genealogy of genes: Non-supervised Orthologous Groups) database generates functional annotations for eukaryotic, prokaryotic and viral sequences. There are also other bioinformatics pipelines and platforms for metagenome analysis that are frequently upgraded with a focus on optimizing metagenome data elucidation (Meyer et al., 2022).

Functional metagenomics

In contrast to sequence-based metagenomics, functional metagenomics uses a very specific function-based “wet-lab” method that enables reliable assessment of a specific function of the microbiome. This assessment is based on the phenotypic selection or screening of clones harboring the DNA sequence encoding that function (Charles et al., 2017). In this approach, the DNA is extracted directly from environmental samples and subsequently cloned into a suitable vector to create DNA libraries. The libraries are inserted into alternative host cells that, once replicated under controlled conditions, can express the target DNA (e.g., screening soil metagenomic libraries for antimicrobial activities) (Biver et al., 2013). This approach is particularly important for the discovery of novel genes encoding microbial functions in soil and can contribute to the annotation of genome and metagenome sequences. Therefore, functional metagenomics has the potential to make major contributions to the study of soil microbiota functioning and the development of biotechnology solutions. The most common expression platform used in functional metagenomics is *Escherichia coli*, however, the quest for robust and flexible screening platforms is an active process in functional metagenomics research (Lewin et al., 2017).

Fig. 2 Schematic diagram of biological molecules targeted from prokaryotic communities by different functional omics technologies. DNA is contained in the nucleoid of prokaryotes, and by sequencing it, it is possible to reveal the taxonomic identity and functional capabilities of the microbiome (e.g., through *metagenomic functional analysis*). Genetic information is transferred in the form of mRNA through the process of DNA transcription. Thus, using high-throughput RNA sequencing (RNA-Seq) it is possible to estimate potential microbial function as changes in the microbial transcriptome (*metatranscriptomics*). Ribosomal RNA (rRNA), which does not harbor relevant functional data, is highly abundant in RNA samples and hence it is usually removed or depleted before sequencing. Cellular messenger RNA (mRNA) then passes to the ribosomes or rRNA, where genetic information is used to synthesize proteins in a process known as translation. The analysis of the complete set of proteins produced by all microbial cells is known as *metaproteomics*. The synthesized proteins, as well as compounds assimilated by the prokaryotic cells, are combined in complex metabolic pathways that take place in the cytoplasm and cell wall. By analyzing the complete metabolites profile, *metabolomics* brings an instantaneous snapshot of the microbial community functioning. Within metabolomics, *volatilomics* constitutes a non-invasive approach to study microbial volatile organic compounds. The multi-level integration and analysis of different omics datasets (*multiomics*) emerges as a promising approach to explore the association between the genotypical and phenotypical features of microbial communities, and their response to environmental factors. Created with BioRender (<https://biorender.com/>).

Functional gene prediction from amplicon-sequence data

Functional gene prediction arose as an alternative to metagenomics sequencing. It consists of predicting microbial functional gene families from their taxonomic compositions inferred from more cost-effective 16S rRNA amplicon sequencing. This approach takes advantage of the evolution of bioinformatics and machine learning algorithms and the abundant characterization of genomes, functional genes and metabolic functions accumulated in databases over the last few decades. Several different pipelines have been proposed including PICRUSt1, PICRUSt2, Piphillin, PanFP, Tax4Fun2, and FAPROTAX (Sun et al., 2020). For example, in PICRUSt2, the amplicon sequence variants (ASVs) are placed into a reference phylogenetic tree containing more than 20,000 full 16S rRNA genes from bacterial and archaeal genomes. From this, the copy numbers of individual gene-families are predicted for each ASV (Douglas et al., 2020). The main limitation of amplicon-based functional prediction is their dependence on existing reference genomes, which can affect the identification of rare environment-specific functions. The accuracy of functional prediction tools will improve as the availability of high-quality genomes from non-clinical (or environmental isolates) increases.

Metatranscriptomics

Metatranscriptomics is the analysis of the whole microbiome gene expression in a particular environment. It is based on shotgun sequencing of RNA from environmental samples and the subsequent analysis of transcriptome profiles. Since mRNA carries out the

genetic information from the DNA to ribosomal sites of protein synthesis, gene expression profiling (i.e., assessing thousands of genes at once) can provide a snapshot of the microbially mediated processes occurring at a particular moment in a specific environment. Therefore, metatranscriptomics can provide information into the underlying functioning of microbial communities and their responses to environmental conditions. The development and popularity of transcriptomics has been attributed to the evolution of RNA sequencing technologies, passing from hybridization-based microarrays to current NGS sequencing technology (e.g., RNA-Seq), which consists of sequencing of complementary DNA (cDNA). Furthermore, RNA-Seq is also evolving from short to long-read RNA-Seq technologies. Long-read RNA-Seq is more cost-effective and more feasible for de novo transcriptome assembly, isoform expression quantification, and in-depth RNA species analysis. The functional annotation of RNA-Seq data can be made directly using reads or using assembled contigs as the annotation of metagenomic data. In addition, several bioinformatics workflows exist for the RNA-seq data analysis. Some of these workflows start with raw sequencing reads, and provide the functional gene profiling and the differentially expressed transcripts (Shakya et al., 2019).

Metaproteomics

Metaproteomics is the high-throughput identification and quantification of all the proteins recovered in an environmental sample. Since proteins are the results of gene expression and because they constitute the largest cellular material, the metaproteomics screening represents a powerful molecular tool to assess microbial community functioning. Metaproteomics also provides information about community composition (in terms of per-species biomass contribution), carbon sources, and the consumption of substrates by community members. Compared to metatranscriptomics, metaproteomics confirms the presence of proteins. This is particularly relevant to study microbial function because mRNA is not always translated into proteins, the amount of protein produced for a given amount of mRNA can vary according to the physiological status of the cell, and post-translational modifications of proteins (e.g., phosphorylation and glycosylation) can be crucial for their function. Metaproteomics uses shotgun liquid chromatography-tandem mass spectrometry (LC-MS/MS) to identify thousands of peptides and proteins per sample. Metaproteomics identifies peptide data by matching it against protein sequence databases and assigning it to proteins or protein groups, which are further assigned to functional groups using various annotation databases. Several bioinformatics pipelines have been developed to characterize and assess the proteomic profile from microbial community samples (e.g., eggNOG-mapper, MEGAN, MetaGOmics, MPA, Unipept, and ProPHAn). These programs differ in several aspects, and each one has its advantages, but there is currently no evidence on which one is more effective than the other (Sajulga et al., 2020).

Metabolomics

Metabolomics is the identification and quantification of the complete set of metabolites present in biological systems. Metabolomics offers unique advantages relative to the other functional profiling strategies and can be highly complementary with other omics interventions. Changes in metabolite concentrations often result from modified enzyme activity or differences in the rates of nutrient consumption and excretion. Thus, metabolite profiling provides a real-time measurement of biochemical activity, taking place in the subject, at the time of sampling. Metabolomics analyses typically involve extracting metabolites, with the addition of internal standards for calibration purposes, and quantification of metabolites. Quantification is carried out by a separation method, such as high-performance liquid chromatography (HPLC) or gas chromatography (GC), coupled with a detection method such as mass spectrometry (MS) or nuclear magnetic resonance (NMR) spectroscopy. Nevertheless, the use of metabolomics in soil science is still in its early stages, despite its extensive use in biomedical science and plant biology, its application in soils remains uncommon. A particular branch that is gaining the interest of the soil-science community, due to its non-invasiveness, is the volatilomics approach. Soil volatilomics deals with the wide array of volatile organic compounds (VOCs) produced or degraded by living organisms in soils. Because soil VOC emissions are largely microbial, dynamic and sensitive to changes in soil conditions, VOC emission profiles are a promising tool to study the metabolic activity of soil microbial communities (Meredith and Tfaily, 2022).

Multimomics

Multimomics is an integrative approach in which multiple omics datasets (e.g., genome, proteome, transcriptome, epigenome, or metabolome) from the same samples are analyzed in parallel and their findings are explored in a complementary way. The multilevel data mining of diverse omics sources enables insight into the linkages between genotype, phenotype, and environmental factors. Multimomics integration approaches could be conceptual (i.e., insight from several omics data sources for a more comprehensive understanding of the biological system) or statistical (i.e., based on mathematical and computational models). Several statistical tools have been proposed for multimomics data integration and analyze, including correlation-based, network-based, Bayesian network-based, machine learning-based, kernel-based, or matrix factorization-based methods (Santiago-Rodriguez and Hollister, 2021); nevertheless, despite multiple advances, multimomics integrative analyses remains challenging. Deep learning is emerging as the most promising class of machine learning algorithms in multimomics data analysis, particularly in large-scale datasets with high dimensionality. It uses multilevel networks algorithms, such as convolutional neural networks (CNNs) and recurrent neural networks (RNNs) to automatically extract meaningful features from the data, and learn intricate relationships (i.e., nonlinear and hierarchical patterns) between different omics datasets that may be difficult to detect using traditional statistical methods

(Picard et al., 2021). An emergent branch of multiomics is single-cell multiomics which encompasses the integrative analysis of diverse single-cell datasets. This approach offers unprecedented resolution into the multiple molecular modalities at the single-cell level. Several recent single-cell data integration approaches have been developed, including Seurat v3, Harmony and iNMF (Gao et al., 2021).

Concluding remarks

We have described a range of methodologies to study soil microbial functions, ranging from traditional techniques that have been used and validated for decades, to novel techniques such as omics tools. While the latter tools harbor great potential, we firmly believe that traditional techniques still have a valuable place in studying soil microbiology. These tools provide affordable and reliable means to evaluate microbial activity in soils, particularly in areas where access to sophisticated omics tools may be limited. Meanwhile, high-throughput tools that collect large volumes of data are becoming not only more accessible but also indispensable to understand the structural and functional complexity of the soil microbiota. As we transition to a future likely driven by more sophisticated technologies and big data, combining the strengths of traditional and novel techniques can provide a more comprehensive understanding of assembly and functions of soil microbial communities. Ultimately, this understanding will allow us to develop effective strategies (e.g., sustainable agricultural practices) to protect and improve soil health.

Abstract

Kinetics describes rates and mechanisms of processes. Microbiological kinetics studies all dynamic behaviors, such as growth, survival, death, mutations, adaptations, product formation, cell cycles, using a combination of experiments and mechanistic mathematical simulations. This chapter introduces the basic terms, variables, and concepts moving from chemical and enzyme kinetics, to unstructured growth models (logistic, Monod, cell quota), structured models simulating self-adaptive microbial behavior (cybernetic, SCM), and to modern genome-scale reconstructions. Effects of environmental factors are illustrated as an interaction of variable pH and temperature with nutrient concentration. The final topic is the near-zero growth of microbial populations prevailing in the biosphere.

Key points

- Microbiological kinetics aims to elucidate the underlying mechanisms of all dynamic manifestations of microbial life by using mechanistic mathematical models. This covers growth, survival and death, mutations, differentiation of cells into forms with contrasting function or activity, product formation, adaptations of metabolism to changing environments, cell cycling and interactions with other organisms.
- The relationship between microbial biomass and cell numbers or length of mycelium is not straightforward, because the mass of individual cells or width of hyphae vary among different organisms and even those of the same species depending on growth conditions.
- As all potentially available nutrients cannot normally be assessed, the focus is on one or few individual compounds or classes of molecules representing the limiting nutrient substrate, i.e., the nutrients that control the growth and activity of the microorganisms investigated.
- Kinetic models are either deterministic (clear, determined and regular processes) or stochastic (dealing with random variables participating in biological processes). The main variables used in deterministic models (concentrations of cell mass, substrates, and products) are the same as in chemical kinetics, whereas stochastic models consider variables such as probabilities, frequency distributions, variance.

- Under natural conditions in the soil, microbial growth is mostly continuous and very slow because of severe nutrient limitations. Even in eutrophic habitats (e.g., the rhizosphere) microorganisms divide no more than 1–2 times per day, whereas in mesotrophic and oligotrophic habitats the doubling time can be months and years.

Nomenclature

$D=F/V$	Chemostat dilution rate
F	Medium feeding rate
K_s	Saturation constant, at $s=K_s$, $\mu=0.5\mu_m$
m	Maintenance term, the catabolic rate $q_s \rightarrow m$, as $\mu \rightarrow 0$
NZG	Near-zero growth under chronic starvation
ODE	Ordinary differential equation
p	Product concentration
PPA	Plant photosynthetic activity
$q_p=(1/x) \cdot dp/dt$	Specific product formation rate (SPR)
$q_s=(1/x) \cdot ds/dt$	Specific substrate uptake rate (SUR)
ROS	Reactive oxygen species
s	Limiting nutrient substrate concentration
SCM	Synthetic Chemostat Model
SGR	Specific growth rate
t	Time
V	Volume of cell culture kept constant in the chemostat
VBNC	Viable but nonculturable cells
x	Cell mass concentration
$Y=-dx/ds$	Cell yield per unit of consumed substrate
$\mu=(1/x) \cdot dx/dt$	SGR calculation
μ_m	Maximum SGR, $\mu \rightarrow \mu_m$ as $s \rightarrow \infty$

Introduction

Kinetics (from the Greek κινετικός, forcing to move) is a branch of natural science that deals with the rates and mechanisms of any processes, physical, chemical, or biological. Microbiological kinetics studies all dynamic manifestations of microbial life: including growth itself, survival and death, mutations, adaptive reconfigurations of metabolism to the changeable environment, products formation, cell cycles, interactions with other microorganisms or microbial hosts (humans, animals, plants), the functional differentiation of cells into active-or-dormant, motile-or-sessile, resistant-or-susceptible. Contrary to descriptive monitoring of process dynamics, kinetic studies attempt to elucidate the underlying mechanisms by using mechanistic mathematical models. The epithet ‘mechanistic’ implies that the respective model translates the postulated essential point of the studied processes into the mathematical equations with variables and coefficients having clear physical, chemical, or biological meaning (contrary to, say, the polynomial regression equations). Then the comparison of observation and the model’s prediction allows researchers to discard incorrect hypotheses or modify them to resolve the interpretive contradictions.

A hypotheses-driven approach to acquiring knowledge is a common part of any [scientific method](#) established in science since at least the 17th century. Testing of hypotheses can be done against a wide range of data and be based on any revealed inconsistencies. The distinctive feature of kinetics is the added strength of the failed dynamic simulation as inconsistency, at the same time typical kinetic study requires an experimental component of high standard, that should be based on reliable *quantitative dynamic* data, such as precise rates measurements under fully controlled experimental conditions or observations of process dynamics over time, preferentially with continuous logging of a set of data interconnected by cause-and-effect relationships. Descriptive information that cannot be expressed numerically is generally not acceptable.

Microbial kinetics is tightly linked to the growth stoichiometry (from the Ancient Greek στοιχείον ‘element’ and μέτρον ‘measure’), which is the quantitative relationship between substrates and the products of the bioprocess. In practical terms, stoichiometry addresses mainly problems of a static nature, like “how much?” and “in what proportion?” while kinetics considers the dynamics and deals with questions like “how fast?” and “by which mechanism?”

There could be reluctance in applying such a biokinetic approach to environmental and biospheric studies, including soil biology, on the basis that these natural systems are too complex for precise rate measurements and fully controlled experimental conditions. This is not true. The complexity of soil as a part of nature does not prevent its deeper understanding by using precise rate measurements and other quantitative methods. Moreover, the combination of mechanistic mathematical simulations with field

observations, laboratory soil incubations, and planted soil microcosms should be highly beneficial for a better understanding of biospheric processes including on-going global climatic changes. It could even be highly beneficial in the practical developments of the mitigation strategies and novel environmental biotechnologies aimed at establishing sustainable land use.

The first chapter in this two-parts series has the objective of introducing the reader to the basic terms, variables and principles of microbiological kinetics that apply equally to industrial bioreactors, laboratory cultures and soil communities. The second chapter focuses on specific applications of the general principles to soil biology. We recommend that an interested reader read both parts, although the sequence order is not critical!

State variables and growth parameters

There are two types of kinetic models, *deterministic* and *stochastic*. The former describes clear, determined, and regular processes. The latter models deal with random variables participating in bioprocesses. The main variables used in deterministic models are the same as in chemical kinetics - concentrations of cell mass, substrates, and products - while stochastic models consider instead probabilities, frequency distributions, variance, etc. For example, a deterministic model can describe the process of N₂-fixation as a function of energy and nutrient supply to the rhizosphere, while a stochastic model considers the probability of rhizobia infecting legume roots for a given frequency distribution of bacteria across the environmental space. Any real biospheric process has both deterministic and stochastic components, so ideally the kinetic model should be a 'hybrid' and contain a deterministic core with a stochastic interface, generating probability distributions and confidence corridors rather than single values or curves.

The major state variables of kinetic models describing microbial processes in nature are summarized in Table 1 and described in detail below.

Amount of microorganisms

Quantitatively, the abundance of microbes can be expressed as biomass (x) or cell numbers (N) of unicellular organisms (bacteria, yeasts, protozoa, fungal spores) per unit of soil or water mass, volume, or surface area. Filamentous organisms (fungi, actinobacteria) are characterized by the length (L) of mycelium and the number of hyphal tips, n , initiated by hyphal branching. Note that n is equivalent to N when branching is equivalent to cell division.

The relationship between x and N or L is not straightforward because the mass of individual cells and width of hyphae vary among different organisms and even for the same species depending on growth conditions. Generally, a plentiful supply of nutrients fosters the formation of bigger cells or wider filaments, whereas starvation causes cells to shrink. To estimate microbial biomass from direct microscopic counting, one should generate several arrays of data: the number $N = [N_1, N_2, \dots, N_n]$ of cells with specifying biovolume $V = [V_1, V_2, \dots, V_n]$, where N_i is the number of cells in the i th volume class V_i and n is the number of such classes, the volumes being calculated from the geometry of all detected cell shapes (spherical, ellipsoid, rod-shaped, irregular). For filamentous microorganisms, one should have arrays of hyphal length $L = [L_1, L_2, \dots, L_m]$ and corresponding hyphal diameters $D = [D_1, D_2, \dots, D_m]$. The total biomass, x , is calculated as a sum of unicellular and mycelial soil microorganisms:

$$x = V \times N \times (1 - \theta) + \pi D^2 \times L \times (1 - \theta) \quad (1)$$

where θ is the cellular water content.

Advanced microscopy (epifluorescence, electron- and atomic force microscopy) and computer-aided image-analysis techniques make cell counting and sizing more accurate and less tedious. Additionally, Fluorescence In Situ Hybridization (FISH) allows targeting of specific taxonomic or functional groups based on the use of RNA-oligonucleotide probes. The total microbial biomass, x , can be estimated by extracting from environmental samples one of the following unique cell constituents: (a) DNA, (b) ATP, (c) membrane phospholipids, (d) microbial cell wall components (chitin for fungi and muramic acid for bacteria), or (e) the sum of labile or extractable C released after natural sample fumigation with chloroform or drying-rewetting (Blagodatskiy et al., 1987).

Selection of either biomass x or cell number N or mycelium length L depends on the specific objectives of the study. Biomass, x , has the obvious advantage in studies of carbon and nutrient cycling, while cell number, N , is preferred in population studies when, say, mutation or plasmid transfer is crucial for the understanding of the studied natural processes.

A large microbial biomass does not necessarily imply a fast growth rate or vice versa, because low abundance could be caused by intensive *elimination* (e.g., washout, chemotactic movement, grazing, and lysis by parasites, see discussion below) of growing cells while high abundance could be due to *migration* of cells from other habitats or accumulation of dormant cells. In the absence of

Table 1 The major dynamic variables used in deterministic kinetic models.

Variable	Symbol	Dimension (examples)
Concentration of cell biomass	x	$\mu\text{g cell mass (g soil)}^{-1}$, $\text{g cell mass m}^{-2}$
Cell number	N	$\text{count (g soil)}^{-1}$
Mycelium length	L	m (g soil)^{-1}
Hyphal tips number	n	$\text{count (g soil)}^{-1}$
Concentration of limiting substrate	s	mg (g soil)^{-1} , $\text{mmol (g soil)}^{-1}$
Concentration of products (CO ₂ , CH ₄ ,...)	p	mg (g soil)^{-1} , $\text{mmol (g soil)}^{-1}$

elimination, the microbial growth rate can be found by recording one of the used quantities (x , N , L , ATP content, etc.) over time t . The *absolute growth rate* is calculated as a simple slope of cell mass x versus time:

$$\frac{dx}{dt} \approx \frac{\Delta x}{\Delta t} = \frac{x_2 - x_1}{t_2 - t_1} \quad (2)$$

This slope normalized to the biomass represents the *specific growth rate* (SGR) of microorganisms, μ :

$$\mu = \frac{1}{x} \frac{dx}{dt} \approx \frac{1}{\bar{x}} \frac{\Delta x}{\Delta t} = \frac{1}{\bar{x}} \times \frac{x_2 - x_1}{t_2 - t_1}, \text{ where } \bar{x} = \frac{x_2 + x_1}{2} \quad (3)$$

In the case of explicit or hidden elimination of microorganisms accompanied microbial growth, the formulae above are no longer valid and the calculated from Eq. (3) SGR should be referred to as the *apparent growth rate*.

The concentration of limiting substrate

Normally we cannot assess all potentially available nutrients and consequently we focus on one or few individual compounds or classes of molecules representing the limiting nutrient substrate, i.e., such nutrient(s) that control the growth and activity of microorganisms in question. Typically, the growth of chemoorganotrophic microorganisms in soil and subsoil is limited by available organic compounds, while photosynthetic microbiota is limited either by light or sources of P, N, or Fe.

The absolute rate of substrate consumption by microorganisms is measured as a time derivative ($-ds/dt$) of the substrate depletion curve, $s(t)$, while the *specific rate of substrate consumption*, q is calculated by normalizing the absolute rate to the instant cell mass concentration, x :

$$q = -\frac{1}{x} \frac{ds}{dt} = Q \frac{s}{K_s + s} \quad (4)$$

Eq. (4) is similar to the Michaelis–Menten equation established in enzymology with parameters Q standing for maximum uptake rate and saturation constant K_s numerically equal to such substrate concentration at which uptake rate $q = 0.5Q$. SGR μ is related to q by a mass balance Eq. (6) (see below) and therefore can be derived from (4) as follows:

$$\mu = Yq = \mu_m \frac{s}{K_s + s} \quad (5)$$

where $\mu_m = YQ$ is the maximal SGR. This expression is known as the Monod equation. Note that both Eqs. (4) and (5) are empirical and should be applied with caution. The substrate uptake rate not only depends on its concentration but also on other environmental factors (temperature, tonicity, pH, etc.) and the physiological state of cells (macromolecular cell composition, proteome expression profile, and other cell qualities). Even more complex is the intracellular machinery responsible for growth (see Section “Models of intermediate complexity”). Therefore Eqs. (4) and (5) should be applied only to relatively simple experiments with s as the only variable and under conditions in which studied cells preserve the same physiological state at all tested values of s .

There are two groups of microbial nutrient substrates: (1) *catabolic substrates* which are sources of energy, and (2) *anabolic or conserved substrates* which are sources of biogenic elements forming cellular material. Examples of catabolic substrates are H_2 for hydrogen-oxidizing microorganisms, NH_4^+ and NO_2^- for nitrifying bacteria, S^0 for sulfur-oxidizing bacteria, and oxidizable or fermentable organic substances for diverse heterotrophic species. Their consumption is accompanied by oxidation and dissipation of chemical substances into waste products, which are no longer reusable as an energy source (H_2O , NO_3^- , SO_4^{2-} , CO_2 , etc.). The anabolic substrates are consumed and incorporated into de novo synthesized cell components, being conserved in biomass; that is why they are referred to as the *conserved substrates*. Contrary to catabolic substrates, the conserved substrates can be reabsorbed after excretion or cell lysis. They include nearly all non-carbon sources of biogenic elements (N, P, K, Mg, Fe, and trace elements), CO_2 for autotrophs, as well as amino acids and growth factors for respective auxotrophic species.

Growth yield

Two variables, cell mass x and substrate concentration s , are linked via stoichiometric parameter *growth yield*:

$$Y = -\frac{dx}{ds} \approx -\frac{\Delta x}{\Delta s} \quad (6)$$

where Δx is the increase in microbial biomass consequent on utilization of the amount Δs of the substrate. Dividing both parts of (6) by xdt gives the relationship between SGR and substrate production:

$$Y = -\frac{dx}{ds} = \frac{1}{x} \frac{dx}{dt} : \frac{1}{x} \frac{ds}{dt} = -\frac{\mu}{q} \quad (7)$$

The reason for Y variation is different for catabolic and anabolic substrates.

Maintenance energy

In the case of energy sources, some fraction of the total substrate flux is diverted from growth per se to meet so-called *maintenance requirements*. Specific maintenance functions are resynthesis of self-degrading macromolecules (proteins, nucleic acids, cell wall), cell motility, osmoregulation, leakage, proofreading, ROS detoxification, etc. The energy balance is described by the following equation:

$$\frac{\text{total energy source uptake}}{q} = \frac{\text{consumption for growth}}{\mu/Y^{\max}} + \frac{\text{consumption for maintenance}}{m} \quad (8)$$

where m is the maintenance coefficient and $Y^{\max}$ is the hypothetical maximum yield that would be observed with zero maintenance, $m = 0$.

To account for the maintenance requirements, Eq. (4) should be modified as follows:

$$q = \frac{\mu}{Y^{\max}} + m = Q \frac{s}{K_s + s} \cdot \mu = \mu_m \frac{s - s^*}{K_s + s} \quad (9)$$

where $s^* = Y^{\max}K_s m$ is the threshold substrate concentration below which cells are not expected to sustain growth, if $s < s^*$, then $\mu < 0$.

If m and $Y^{\max}$ are constants, then the plot of q versus μ should be a straight line with y -intercept equal to m . Such a plot is the only possible experimental way of finding the maintenance term m . In practice, a chemostat culture of the tested microorganism is run sequentially at several dilution rates until steady-state ($D = \mu$) is established; at each D steady-state biomass and some catabolic rate (respiration, heat production, uptake of the energy source, etc.) are monitored and q plotted versus $D = \mu$ as illustrated in Fig. 1. Note that the described technique is indirect and time-consuming but unfortunately there are no *direct ways* to estimate the maintenance as a part of cellular energy balance. Numerous maintenance processes (osmoregulation, resynthesis, and repair of damaged polymers, stress-response) are mixed up with the growth-associated processes and could not be accurately translated into the energetic cost. The only manifestation of the maintenance is a decrease of apparent cell yield at low SGR. Under very deep nutrient limitation typical for the soil environment, the maintenance term m can no longer be considered as a constant, so the Eq. (9) must be replaced by more advanced kinetic models, see the Section “Near-zero growth kinetics.”

Energy overflow

Maintenance requirements should be distinguished from other non-productive use of energy called *wasteful respiration* or *energy-spilling reactions*. They are observed under several special circumstances: (i) when growth is energy-sufficient but limited by anabolic substrates (sources of N, P, K, Fe, vitamins, etc.); (ii) over extended lag-phase of batch culture; (iii) in transient experiments when starving cells are brought to rich medium and (iv) when cells are exposed to uncoupling inhibitors. A common feature of all the listed processes is so-called *energy overflow*: the energy flux significantly exceeds the level required for biosynthetic processes constrained by inhibitors or a depleted pool of ribosomes or by other than energy source nutrients. As a result, the diversion of energy consumption from growth is much greater than expected from the basic maintenance functions observed in the energy-limited chemostat culture. Note that the energy overflow has been observed in laboratory experiments; this phenomenon has not been demonstrated in situ.

Fig. 1 Two ways of representing the maintenance term. (A) The Monod-Pirt model assumes the constancy of the maintenance term. The tested microorganisms are grown at several dilution rates D in a chemostat limited by the energy source. The specific catabolic rates q_s (respiration, catabolic substrate uptake) are plotted vs $D = \mu$, and fitted to Eq. (9) giving $1/Y^{\max}$ (slope) and the maintenance coefficient, m (intercept and the dotted line). (B) The same plot is simulated by a more realistic SCM model, which allows adaptive self-regulation of the maintenance term. Note a progressive decrease in maintenance with slowing growth. Modified from Panikov NS (1995) *Microbial Growth Kinetics*. The Netherlands: Springer. 378 p.

Cell quota. Variation of yield on anabolic substrates

Cell yield on anabolic substrates varies mainly as a result of alterations in biomass chemical composition as expressed by the parameter σ_s , the intracellular content of a deficient element, or *cell quota*. For example, the variation in N content in bacteria from 5% to 15% gives the σ_s range 0.05–0.15 g N (g cell mass)⁻¹. For most known cases, the quota σ_s increases parallel to growth acceleration, because the higher growth rate requires higher *intracellular content* of proteins and RNA (contain N, P, S) as well as K⁺, Mg²⁺ and vitamins participating in primary metabolic reactions. The yield and cell quota are inversely related to each other, e.g., small N-content ($\sigma_N = 0.05$ g N/g) corresponds to large cell yield ($Y_N = 1/\sigma_N = 20$ g cell per g of N utilized), large N-content in rapidly growing cells can be attained only with a small cell yield ($Y_N = 1/0.15 = 6.67$ g cell/g N) (Fig. 2). The principal difference between Y and inverse σ ($1/\sigma$) is that the first stoichiometric parameter is subjected to instantaneous changes as dependent on s level in various transient shift-up or shift-down processes, while the second parameter is essentially slower required deep reconfiguration in cellular composition.

Products

There could be *intermediate* and *end* metabolic products accompanying microbial growth. The typical intermediates of the glycolytic and the Entner–Doudoroff pathways are:

- glucose $\rightarrow$ 2 pyruvate⁻ + 2H⁺;
- glucose $\rightarrow$ gluconic acid $\rightarrow$ pyruvate;
- pyruvate $\rightarrow$ acetate + CO₂

biological activity due to the wide availability of gas analyzers (GC, IR- and MS). For the case of aerobic decomposition, the measured CO₂ evolution is a significant fraction of the C budget as described by the following mass-balance equation:

The only major end product of aerobic microbial decomposition is CO₂. Under anaerobic conditions, the spectrum of products is much wider and includes several organic acids, alcohols, and ketones, H₂, CO₂, CH₄, and various reduced inorganic compounds (S²⁻, Fe²⁺...). CO₂ evolution rate is probably the most popular parameter to characterize soil

$$\frac{\Delta C-s}{\Delta t} = \frac{\Delta C-x}{\Delta t} + \frac{\Delta C-CO_2}{\Delta t} + \frac{\Delta C-p}{\Delta t} \quad (10)$$

Division by time increment dt gives:

$$\frac{ds}{dt} = \frac{dx}{dt} + \frac{d[CO_2]}{dt} + \frac{dp}{dt} \quad (11)$$

Thus, microbial consumption of C-substrate is the sum of growth, respiration, and product formation, if all four variables are expressed in the same mass-C units, e.g., mg C/g soil. Based on such a C-balance, we can estimate with confidence some variables that are hard to measure directly. For example, cell mass, x in a laboratory soil incubation study can be calculated as the difference between the amount of initially added substrate s_0 and the time-dependent qualities of residual substrate s and products CO₂ + p . However, it would be incorrect to identify the CO₂ evolution rate alone with total soil decomposition, as some degraded C is incorporated into soil organisms or their extracellular products.

Fig. 2 Variation of the cell mass yield on catabolic (A) and anabolic (B) substrates related to SGR. All curves were calculated using SCM or its simplified versions. Modified from Panikov NS (1995) *Microbial Growth Kinetics*. The Netherlands: Springer, 378 p.

Kinetic models of microbial bioprocesses

Chemical and enzyme kinetics

Microbial growth is a complex bioprocess that includes numerous enzymatic and chemical reactions. The basic equations of chemical and enzymatic kinetics are presented in Table 2. There are notions of *molecularity* (the number of molecules that are altered in the reaction) and *kinetic order*, which should not be confused. According to the *law of mass action*, the rate of the chemical reaction is directly proportional to the product of the activities or concentrations of the reactants:

$$\frac{ds}{dt} = -k_n s^n \quad (12)$$

where n is the kinetic order, and k_n is a rate constant. For a simple single-step reaction, the order is generally the same as the molecularity. For a complex reaction involving a sequence of unimolecular and bimolecular steps, the molecularity is not the same as its order. Reactions of molecularity greater than 2 are common, but reactions of order greater than 2 are very rare. For instance, a trimolecular reaction, such as $A + B + C \rightarrow P$, as a rule proceeds through two elementary steps, $A + B \rightarrow X$ and $X + C \rightarrow P$, each of which are of the second or first order. Table 2 gives expressions for three typical cases (zero, first and second order), the left column shows reaction rate as a function of reactant concentration (s), the right column presents results of integration under the initial conditions: $s = s_0$ at time $t = 0$.

A unique feature of all enzymatic reactions is reversible formation of the intermediate enzyme-substrate complex $ES: E + S \xrightleftharpoons[k_{-1}]{k_1} ES \xrightarrow{k_2} E + P$, where k_{-1} and k_2 are the first order and k_1 is the second order rate constants. Under steady-state assumption

Table 2 Basic equations of chemical and enzyme kinetics.

Rate vs. substrate concentration		Reaction progress, $s(t)$		
Zero-order				
		$s = s_0 - kt$	Residual substrate, linear scale, log-scale	
$\frac{ds}{dt} = -k$				
First-order				
		$s = s_0 e^{-kt}$		
$\frac{ds}{dt} = -ks$				
Second order				
		$s = \frac{s_0}{1 + ks_0 t}$		
$\frac{ds}{dt} = -ks^2$				
Mixed order, Michaelis-Menten equation				
		$K_m \ln\left(\frac{s_0}{s}\right) + s_0 - s = Vt$		
$K_m = \frac{k_{-1} + k_2}{k_1}, V = k_2[E]$ $\frac{ds}{dt} = -\frac{Vs}{K_m + s}$				
Substrate concentration, mM		Time, min		

(constancy of ES concentration over time), this mechanism is translated into the Michaelis-Menten equation (Table 2, the bottom line), predicting a mixed reaction order (the first order at small s and zero order at large s), a unique kinetic feature of reactions driven by enzymes. Based on experimental data including the reactant depletion curve $s(t)$, we can distinguish abiotic vs enzymatic reactions and identify the reaction kinetic order.

Exponential growth

It is the simplest growth pattern displayed by all microorganisms (binary dividing bacteria, budding yeasts, fungal mycelium). Exponential growth is observed temporarily under favorable physicochemical conditions before depletion of nutrient substrates and accumulation of self-inhibitory products. The basic assumption is that the current growth rate is proportional to the instant cell mass, x , the quotient μ remaining constant:

$$\frac{dx}{dt} = \mu x \quad (13)$$

The integration of (13) at initial condition, $x = x_0$ at time $t = 0$, gives the exponential equation:

$$x = x_0 e^{\mu t} \text{ or } \ln x = \ln x_0 + \mu t \quad (14)$$

Any metabolic rate, such as intensity of methane production, the evolution of CO_2 , rate of sulfate reduction recorded in microbial culture or nutrient-amended soil samples, is proportional to the growth rate of microorganisms:

$$\begin{array}{ccccc} \text{Metabolic rate} & & \text{Stoichiometric factor} & & \text{Cell growth} \\ \frac{dp}{dt} & = & \frac{1}{Y'} & \times & \frac{dx}{dt} \\ & & & & = \mu \frac{x}{Y'} = \mu \frac{x_0}{Y'} e^{\mu t} = A e^{\mu t} \end{array} \quad (15)$$

where p is the concentration of metabolic product expressed for simplicity in the same carbon units as biomass, mg C per g sample, and Y' is the cell mass yield per mass unit of the metabolic product. Integration of (15) under initial condition $p = 0$ at $t = 0$ gives:

$$p = \frac{x_0}{Y'} (e^{\mu t} - 1) = B(e^{\mu t} - 1) \quad (16)$$

Comparing (14) and (16) we see that x and p time courses are not identical, although both imply exponential cell growth, the $p(t)$ curve deviates from the exponential law, especially at small t . In particular, the “ $\ln x - t$ ” plot is linear, but the plot of $\ln p$ vs t is not. As t increases, the difference progressively decreases. However, the rate of product formation, e.g., soil respiration measured as $\text{mg CO}_2\text{-C/h/g soil}$, follows the exponential pattern (Eq. 14).

Logistic growth

In contrast to the exponential growth equation described above, the logistic equation established by Verhulst in 1838 sets an upper limit for microbial growth by assuming that SGR is dependent on the microbial density, x :

$$\frac{dx}{dt} = \mu(x)x = (\mu - a)x \left(1 - \frac{x}{x_m}\right) = rx \left(1 - \frac{x}{K}\right) \quad (17)$$

where x_m is the upper limits of cell mass. In ecological literature, x_m is called the *carrying capacity* of the ecosystem, K , and the difference between true growth rate, μ , and mortality rate, a , is presented as apparent growth rate, r . This equation mimics the S-shaped growth curve frequently observed in nature. However, it represents nothing more than an empirical relationship ignoring real ecological mechanisms and interactions; note that parameters of logistic equation r and K cannot be predicted *before* actual observation.

Monod model

This model was developed by a famous French scientist in 1941 but it is still very popular due to its elegant simplicity. There are two basic premises: (a) the SGR is dependent on the concentration of limiting substrate (Eq. 4); and (b) biomass formation is linked to substrate uptake by mass-conservation condition (Eq. 6):

$$\begin{array}{l} \frac{dx}{dt} = \mu(s)x = \mu_m \frac{s}{K_s + s} x \\ \frac{ds}{dt} = -\frac{1}{Y} \frac{dx}{dt} \end{array} \quad (18)$$

Equation set (18) contains three parameters: yield Y , maximal SGR μ_m , and saturation constant K_s , which can be thought of as ‘ID’ for individual organisms and used to predict their growth dynamics. Remarkably, this model was used to develop a chemostat theory before actual experiments with continuous culture had been undertaken, one of the very rare events in the history of mathematical biology! For this purpose, the equation set (18) was modified as follows:

$$\begin{aligned}\frac{dx}{dt} &= (\mu - D)x, \mu = \mu_m \frac{s}{K_s + s} \\ \frac{ds}{dt} &= D(s_r - s) - \frac{1}{Y}\mu x, D = \frac{F}{V},\end{aligned}\quad (19)$$

where s_r is the concentration of limiting substrate in the fed fresh medium delivered with pump from a reservoir, F is the pumping rate (cm^3/h), V is culture volume (cm^3), and D is the dilution rate defined as the ratio $D=F/V$, h^{-1} . The model predicted several counter-intuitive features of the chemostat, e.g., that SGR can be set up by an experimentalist by changing the medium flow at any values between 0 and μ_m (before specific growth was believed to be a constant μ_m) and that growth rates depend on s (the *residual* nutrient concentration in bioreactor) rather than on s_r (the nutrient concentration in the feed medium).

However, the Monod model fails to explain many dynamic phenomena observed experimentally, namely: lag-phase, death of starving cells, product formation, and any kind of adaptive changes in the microbial population, such as induction-repression of enzymes, yield variation, changes in the cell RNA content, etc. These gaps were intended to be filled by the structured models.

Cell quota model

The model is based on the empirical observation that SGR is proportional to the intracellular content of a deficient element σ , such as N, P, Fe, and other conserved nutrient substrates (Droop, 1973). As applied to the chemostat culture, it contains the same two variables (x and s) as Eq. (19), but a different expression for specific growth rate:

$$\begin{aligned}\frac{dx}{dt} &= \mu x - Dx \\ \frac{ds}{dt} &= D(s_r - s) - \mu x \sigma \\ \mu &= \frac{\mu_m \sigma_m (\sigma - \sigma_0)}{\sigma (\sigma_m - \sigma_0)}\end{aligned}\quad (20)$$

It was the first attempt to express the relationship between SGR and cell quota, the variable characterizing the chemical composition of the cell biomass. However, it is wrong to consider cell quota as an independent variable. As a matter of fact, σ itself is a function of the environmental factors, such as the concentration of respective sources of biogenic elements in situ.

Structured models

These models explicitly describe variations in cell composition (Fredrickson, 1976), they include mass balance equations not only for *external* substrates and products concentrations but also several *intracellular* components, $C_1, C_2, \dots, C_n$, such as DNA, RNA, proteins, cell wall constituents, reserved polysaccharides, ATP-pool, etc. For each variable C_i a differential equation is written which accounts for all sources, r_+ , and sinks, r_- , as well as its dilution due to cell mass expansion (growth),

$$\frac{dC_i}{dt} = r_+(s, C_1, \dots, C_n) - r_-(s, C_1, \dots, C_n) - \mu C_i \quad (21)$$

The earliest structured models contained just 2–3 highly aggregated internal variables, e.g., the total content of cellular proteins, RNA, and DNA. More advanced models covered up to 50 real cellular constituents and the lumped variables such as pools of amino acids and nucleotides, rNTP and dNTP, cell wall precursors, stable (rRNA), and short-lived RNAs (mRNA and tRNA), regulatory metabolite ppGpp, glycogen, peptidoglycan. These structured models produced modest results and never gained a wide recognition blamed by biochemists for oversimplification of real microbial metabolism and by modelers for extreme complexity. Two of their main disadvantages were (i) a subjective selection of internal variables, and (ii) a problem of experimental verification of the aggregated data.

Genome-scale models (GEM)

The ambitious goal of GEM is the accurate prediction of the phenotype from the respective genotype under specified environmental conditions. High throughput genome sequencing makes it possible to screen nearly all cultivable microorganisms of whatsoever medical, industrial, or environmental significance, including soil isolates. Presently, NCBI lists more than 300,000 completed whole-genome projects including ~7500 sequenced fungal species and more than 31,000 prokaryotic (archaeal and bacterial) species. Soil microbial communities are still underrepresented in culture collections because most soil inhabitants resist isolation. However, the metagenomic approach (shotgun sequencing of the DNA directly extracted from the soil) potentially allows in silico reconstruction of phenotypes for any microorganisms, well-known or mysterious uncultivable species. We are still far away from this ultimate goal, but in the case of success, GEMs would be able to reconstruct their growth dynamics under a specified state of the environment.

Fig. 3 Simplified view on the bacterial genome structure through the prism of GEM-modeling.

The progress of GEM development is impressive. The first GEMs were constructed for the simplest parasitic bacteria and *E. coli* in 1995–1997, and then the number of GEM publications has [risen exponentially](#). GEM is the metabolic network reconstruction. Contrary to the structured models above, GEM uses real individual intracellular metabolites and metabolic reactions extracted from genomic data.

GEMs cover only the part of the genome, mostly up to 35%. From a modeling perspective, there are four distinct parts of the genome (Fig. 3): (i) junk material and sequencing errors needed to be removed (blue background), (ii) the **M-matrix** (M for metabolism) standing for genes encoding enzymes catalyzing the entire intermediary metabolism, which is about one-third in prokaryotes and smaller fraction in eukaryotes; (iii) the **E-matrix** (E for expression) accommodating genes encoding enzymes and RNAs responsible for proteins synthesis, transcription, and translation; (iv) finally, the **O-matrix** (O for operon) containing the transcriptional regulatory network, a part of global regulatory machinery orchestrating cellular functions via transcription factors, TFs. Respective GEMs are called **M**-, **E**- and **O**-models. Reconstruction of metabolic networks (M-models) is now a well-established process. The E-models have recently been started by using a similar approach and are produced as combined **ME**-models. Both models convert genomic data into stoichiometric matrices of intermediate (M-matrix) and biosynthetic reactions (E-matrix) that are made interactive. Unfortunately, there is no way to predict in theory or based on sequence similarity the functionality of the O-matrix, ‘the brain’ of the metabolic network. Instead, GEMs apply the optimality principle, assuming that natural regulation of metabolic network is performed in such a way that maximizes the growth rate of microorganisms under given growth conditions. There could be other objective functions, e.g., the minimizing cost of protein biosynthesis, minimizing the ATP-pool size or the energy consumption.

The most popular is the M-models called the Flux Balance Analysis (FBA). It seeks only the steady-state solutions for metabolic fluxes and uses constraints to define a closed solution space for the flux vectors by setting up the low and high boundaries for each flux. Additional constraints are coming from the reaction thermodynamics as well as from the metabolomic, transcriptomic, or proteomic data.

The starting point of FBA is the annotated genome sequence. The product of each gene is annotated by homology searches to identify all the metabolic enzymes. It happens frequently that some enzymes in a known pathway are missing, so other reactions are added to close the mass balance. In addition to enzymatic reactions, all transport mechanisms must be accounted for, such as diffusion, active or facilitated transport through membrane, and secretion of exometabolites. In the next step, a dynamic mass balance is derived for all the metabolites using a matrix notation:

$$\frac{d\mathbf{X}}{dt} = \mathbf{S} \times \mathbf{v} \quad (22)$$

where $\mathbf{X}$ is the vector of cellular metabolites, $\mathbf{S}$ is the stoichiometric matrix and $\mathbf{v}$ is the matrix of the fluxes.

The main FBA advantage is its computational efficiency: the COBRA toolbox in Matlab or COBRApy in Python installed on a regular laptop executes full-size M-models (thousands of metabolic reactions) in a few seconds. The FBA is not designed for dynamic simulations and cannot present growth as a time series of x , s , and p to demonstrate the agreement. Instead, it produces the metabolic map with fluxes for each metabolic reaction. It correctly reproduces specific rates of unlimited growth (observed in the batch culture exponential phase), metabolic reconfigurations after switching from one C-source to another, from aerobic to anoxic growth conditions; it also accurately predicts genes essentiality and the impact of the gene knockdown on metabolic flows including the exometabolic products that is especially valuable for bioengineering.

The dynamic FBA (dFBA) applies the *quasi-steady-state* approximation. The metabolic fluxes can be differentiated into slow and fast categories as dependent on reaction volume. The exchange reactions between cell and environment (nutrient uptake and product release) take place in the volume range 10^0 – 10^4 cm³. The *intracellular* metabolic reactions occur in a much smaller volume of a single cell, 10^{-8} – 10^{-9} cm³. The volumetric difference 10^8 – 10^{13} times implies that intracellular reactions can be safely assumed to be at a steady-state, and therefore the flux distribution can be resolved by the FBA. Few remaining slow exchange variables are to be numerically solved as a set of ordinary differential equations (ODEs). Numerous dFBA models were developed to simulate growth dynamics of the model (*Saccharomyces cerevisiae* and *E. coli*) and industrially important organisms, some of which (e.g., *Pseudomonas putida*) are used for soil remediation.

The ME-models and the whole-cell models aimed to simulate a self-regulatory behavior of microorganisms under fluctuating environment have been constructed for smallest parasitic prokaryotes as well as for the two best studied organisms, *E. coli* and baker yeasts. Unfortunately, they remain too cumbersome for execution and too modest in discovery of the emergent systems qualities of the cell (Panikov, 2021). Indisputably, GEMs are the most promising tools in biokinetic studies, but their practical implementation to environmental sciences is still not possible.

Models of intermediate complexity

Several growth models occupy an intermediate position between oversimplified Monod-type equations and gigantic genome-scale metabolic reconstructions operating with thousands of variables. In real life, we face a necessity to have a ‘fundamentally correct’ and compact representation of microbial dynamics that can be instantly solved with regular computers and standard software. A perfect equivalent would be the [ideal gas law](#) in physical chemistry, the simplified but dependable model reproduces correctly the behavior of many gases under many conditions. It would be wrong to simplify GEM by selecting a limited subset of genes (see above a failure of the structured models), a more promising option would be to rely on compact models able to reproduce the behavior of *an ideal cell* in a real variable environment. A loose analogy with ideal gas (having zero intermolecular attractions) allows us to picture such a cell as free from numerous specific details and having only two essential functional qualities – *to reproduce itself and adapt to the fluctuating environment by conditional expression of subcellular structures*. From the kinetic perspective, both qualities are unique to cells and absent in enzymes, which do not proliferate or change their composition. There is no problem with reproduction, it is manifested kinetically as the exponential x increases with the constant SGR under permanently optimal conditions (Eqs. 13 and 14). Under fluctuating conditions, we typically observe increases or decreases of SGR parallel to changes in the macromolecular composition of cells (MMCC), including proteomic and transcriptomic profiles, the composition of lipids, metabolic intermediates, and other results of the *omics* molecular inventories. We apply here the term ‘models of intermediate complexity’ to those non-GEM growth models that make a very important step forwards to the genome-scale level by attempting to relate the macroscopic growth kinetics (SGR, yield, respiration, maintenance, etc.) with MMCC and variable environmental conditions. There are two types of such models: (i) the cybernetic model and (ii) the synthetic chemostat model (SCM). Both reached some success in the simulation of the self-regulated behavior of cells in response to environmental changes.

The cybernetic models (Kompala et al., 1986) were introduced initially as simple structured models, the word ‘cybernetic’ implying a parallel between a living cell and electronic gadgets, both dealing with circular causalities and feedback. Two cybernetic variables were incorporated as Boolean ON/OFF switches into the conventional Monod-style growth models applied to situations when the cell must take a decision, e.g., select the preferential substrate in the mixture of glucose and lactose:

$$\begin{aligned}\frac{dx}{dt} &= x \sum_{i=1}^2 \mu_i v_i - Dx; v_i = \frac{\mu_i}{\max(\mu_i)} \\ \frac{ds_i}{dt} &= D(s_{ri} - s_i) - x \left(\frac{\mu_i v_i}{Y_i} + m_i v_{mi} \right) \\ \frac{de_i}{dt} &= q_i u_i - \mu e_i; u_i = \frac{\mu_i}{\mu}; \mu = \sum_{i=1}^2 \mu_{mi} e_i \frac{s_i}{K_{si} + s_i}\end{aligned}\quad (23)$$

Here the elements of MMCC are two transporters e_1 and e_2 specializing on uptake of glucose and lactose respectively. The cybernetic variables regulate transcription (u) and uptake rates (v) as dependent on the difference between the current values of μ_1 and μ_2 , the SGR on each of the competing substrates: $v_1 = \begin{cases} 1, & \text{if } \mu_2 < \mu_1 \\ 0, & \text{if } \mu_2 \geq \mu_1 \end{cases}$; $v_2 = \begin{cases} 0, & \text{if } \mu_2 < \mu_1 \\ 1, & \text{if } \mu_2 \geq \mu_1 \end{cases}$.

Not surprisingly, the model successfully predicted a correct choice of glucose as a preferential substrate with the following diauxic pattern, unfortunately only in the simplest setup of the canonic exponential phase with constant SGR and MMCC. The modern cybernetic models use similar v and u cybernetic variables but are scaled up to the genomic level (Kim et al., 2008; Song and Ramkrishna, 2011). Their value as a self-dependent subtype of GEM is questionable because of the artificial nature of these operational variables. So far, the cybernetic models have not been applied to complex microbial biodynamics, such as non-steady state and unbalanced growth in bioreactors or in situ.

The SCM (Panikov, 1995) has been built upon all the chemostat models listed above, including the Monod model and its modifications, cell quota and structured models (that explains the epithet ‘synthetic’). The basic SCM contains three differential equations for the limiting substrate, s , cell biomass, x , and the r -variable compactly characterizing the MMCC (the ‘quality’ of cells):

$$\frac{ds}{dt} = D(s_r - s) - q_s x, q_s = rQ \frac{s}{K_s + s} \quad (24)$$

$$\frac{dx}{dt} = \mu x - Dx, \mu = Y(q_s - m) \quad (25)$$

$$\frac{dr}{dt} = \mu \left(\frac{s}{K_r + s} - r \right) \quad (26)$$

The r -variable (Eq. 26) has been introduced as follows. There are at least two functional groups of cellular constituents: the content of P-components correlates with SGR because they participate in the Primary metabolic reactions (ribosomes, key biosynthetic

enzymes). Other conditionally-expressed cell constituents are associated with the secondary metabolism responsible for cell survival (U-components) under stresses, and their content negatively correlates with SGR. Examples of U-components are enzymes involved in drug resistance and synthesis of antibiotics, protective pigments, reserved polymers, high-affinity transporters, etc. The first and second groups are combined respectively into vectors $\mathbf{P}$ and $\mathbf{U}$ satisfying conservation condition $\mathbf{P} + \mathbf{U} = 1.0$ if each P_i and U_i are normalized to cell dry mass (the contribution of small molecules is neglected for clarity). The constitutive (unchangeable) parts are denoted as $P_i^{\min}$ and $U_i^{\min}$ while $P_i^{\max}$ and $U_i^{\max}$ are the upper limits respectively. The SCM makes three assumptions: (1) all P-components change in response to environmental signal synchronously and in the same direction (otherwise sustainable growth would be impossible); (2) the main environmental signal controlling the vectors $\mathbf{P}$ and $\mathbf{U}$ expression is the concentration of limiting substrate, s that is sensed by cells; (3) the expression degree is approximated by a hyperbolic function of s :

$$\mathbf{P} + \mathbf{U} = \begin{bmatrix} P_1^{\min} \\ \dots \\ P_n^{\min} \end{bmatrix} + \begin{bmatrix} U_1^{\min} \\ \dots \\ U_m^{\min} \end{bmatrix} + r \begin{bmatrix} P_1^{\max} - P_1^{\min} \\ \dots \\ P_n^{\max} - P_n^{\min} \end{bmatrix} + (1-r) \begin{bmatrix} U_1^{\max} - U_1^{\min} \\ \dots \\ U_m^{\max} - U_m^{\min} \end{bmatrix}; \quad r = \frac{\bar{s}}{K_r + \bar{s}} \quad (27)$$

Constitutive part Changeable P part Changeable U part Steady state r

where r has been introduced as a common quotient to all elements of the vector $\mathbf{P}$. It is a scalar function of s , which varies between 0 (long-term starvation) and 1.0 (established unlimited growth) and expresses the quality of cells: the higher is r , the higher is the content of P-components. These assumptions and expression 27 agree with available chemostat data on the growth rate driven changes in the composition of cells (Fig. 4A) and the observed patterns in gene expression (Panikov, 2021) as well as with the well-established knowledge on the master role of transcription factors orchestrating simultaneous transcription of the long list (100–1000) genes responsible for stress resistance (Hengge-Aronis, 2002; Gasch et al., 2000). Thus, gene expression is likely to vary in a well-coordinated manner and SCM accurately mimics this trend although unable to specify individual conditionally expressed macromolecules. Nonetheless, the combining kinetic terms with MMCC improves significantly the predictive power of the SCM. The model can reproduce and predict before the actual experiment, the time course of batch culture (Fig. 4B) starting from the initial lag phase to the following growth phases leading eventually to starvation death of cells in depleted culture. To run the simulation,

Fig. 4 Simulation success of the SCM model. (A) Cell composition of *A. aerogenes* as dependent on dilution rate in a NH_4^+ -limited chemostat culture (Tempest et al., 1967). (B) Batch growth of *Schwanniomyces vanrijiae* on the minimal glucose–mineral medium. VBNC stands for the viable-but-not-cultivable cells (Panikov, 2019). (C) The shift-up experiment in a chemostat culture of *Aerobacter aerogenes* limited by glycerol; at time zero, the dilution rate was changed from 0.004 to 0.24 h^{-1} (Tempest et al., 1967). one needs to know the initial conditions (x_o , s_o , r_o) and the basic growth parameters as a set of constant coefficients specific to every cultivable microorganism. Further, the SCM successfully simulates the steady-state and transient growth in various continuous bioprocesses (chemostat, turbidostat, pH-stat, retentostat and dialysis culture), including the most challenging transient shift-up and shift-down regimes (Fig. 4C). This model will be mostly used below for analysis of the effect of environmental factors on microbial growth, as well as in the linked chapter, where it is devoted to soil applications.

Growth dependence on environmental factors

The factors affecting growing cells in culture and in situ can be physical (temperature, tonicity, moisture content, texture, conductivity, gas exchange rates); chemical (pH, Eh, ionic strength, surface chemistry of particulate matter, medium or soil solution composition); and biological, e.g., the positive, or negative interactions with other microorganisms or a host.

Hierarchy of factors, the primary significance of the nutrient resources

In the ecological literature, all factors are viewed as important, their priority is dependent on local circumstances. For example, the radiation regime and temperature are supposed to be the key environmental factors in polar ecosystems, water availability in deserts, metals toxicity in areas affected by industrial pollution, salinity in salt marsh soil, and so on. However, from the biokinetic perspective, the *nutritional* factor stands alone as a *primary* factor under any circumstances, while the rest of the *modifying* factors (temperature, pH, Eh, pressure, precipitation, moisture content, and many others) can accelerate, slow or stop a microbial process but can never produce new cell mass. The state variables representing the nutritional factor, such as s , the limiting substrate concentration, must be present in any kinetic model of microbial growth. The variables characterizing the modifying factors are incorporated into specialized kinetic models focusing on a particular problem. The following three arguments justify the stated difference between the primary and modifying factors. *First*, the nutrients participate in growth stoichiometry, they are reactants initiating the entire cellular metabolic network eventually producing new cells and products. The modifying factors do not participate in growth stoichiometry or mass-balance of microbial growth. *Second*, contrary to most modifying factors that characterize the *state* of the environment, nutrients represent the (actually or potentially) limited *consumable resources* shared between various competitors: coexisting species in communities, subpopulations of the same species (e.g., the spontaneous mutant vs wild parental cells), alternative pathways of the cellular metabolic network. It makes the nutritional factor especially influential in the simulations of complex systems aimed at the selection of the most probable scenario from numerous alternative options. *Third*, the temperature and other modifying environmental factors are important; however, simulation of their action can be meaningful only in combination with the nutritional factors. The opposite is not true: the effect of nutrients can be fruitfully explored separately from the modifying factors, provided they remain constant. The reason is that microbial response to any environmental factor heavily depends on the metabolic status of cells, gene expression profile, and proteome – all internal characteristics being shaped by the nutritional status. Specifically, the stress response to heat, cold, or drugs, is mediated by chaperones and other reparation biomolecules that require energy and biosynthetic precursors. Interestingly, the maximal stress resistance is observed not under plentiful nutrient supply but rather under deep substrate limitations (Panikov et al., 2015), a phenomenon simulated and explained by SCM.

Below we demonstrate how two archetype modifying factors (pH and temperature) interact with the nutritional factor in the characterization of growth kinetics. The final example is a special case of the exceptionally deep nutrient limitation neglected in laboratory studies and widely occurring in nature responsible for so-called, near-zero microbial growth (NZG).

Effects of pH

In enzymology, the effect of pH is explained by the ionization of several functional groups within the active center. The first assumption is that an enzyme is the dibasic acid H_2E , which undergoes dissociation:

The second assumption is that only the HE^- form is active, it cuts the reaction rate by the pH-dependent factor $\theta = [HE^-]/([H_2E] + [HE^-] + [E^{2-}])$, where all three concentrations can be expressed via $[H^+]$, K_1 and K_2 . The final assumption is that all cellular enzymes have similar pH profiles, then the proposed mechanism can be applied to the SGR:

$$\mu_{pH} = \mu_m \theta = \mu_m \frac{K_1 [H^+]}{[H^+]^2 + K_1 ([H^+] + K_2)} \quad (29)$$

Eq. (29) does not account other than pH restriction factors. So, in the case of nutrient limitation and non-optimal temperature, we should add respectively Eqs. (18), (19), (24)–(26) and (36) (see below) in a multiplicative way. Eq. (29) reproduces the experimentally observed symmetrical bell-shaped curve with a maximum at $(pK_1 + pK_2)/2$ (Fig. 5). There could be other

Fig. 5 Effect of pH on microbial growth, Eq. (28).

mechanisms involved at the cellular level. However, for practical purposes, Eq. (29) works reasonably well in finding the optimal pH, especially useful when data points are rare and scattered.

Contrary to the most enzymatic reactions, microbial growth is accompanied by dramatic pH changes. A widely spread misconception is that growth is predetermined to release acidic metabolites (acetic, pyruvic, citric acids) produced in glycolysis and TCA cycles. This idea is not accurate, microbial growth can be associated with either metabolic acidification or alkalization and is dependent on media composition; acidic metabolites are not the only reason for pH drop, it is better to state that growth is accompanied by uptake and release of ionized species which can cause the acid-base disbalance. Very often, the main reason for disbalance is the intensive uptake of the N-source rather than release of organic acids. Let us identify where the problem lies.

The starting point in the understanding and prediction of the acid-base disbalance, is to draft the stoichiometric equation of bacterial growth. Cell biomass is represented as a pseudo-compound with the empirical formula $\text{CH}_h\text{O}_o\text{N}_n$ derived from the average elemental composition (below the *E. coli* data are used) and normalized to the C-atoms. The lower-case indexes h, o, and n indicate the amount (very rarely the integer as in individual chemical compounds) of respective elements H, O, and N per one C atom. Other macro-elements (P, K, S, Ca, Mg, ...) and trace elements are ignored because of their minor effect on the ionic status of a typical microbial culture. The following three stoichiometric equations are just examples. They are complete analogs of well-known chemical equations, each side must represent the same number of atoms, and the same holds true for the total electric charge (condition of neutrality) through conversion of three 'reactants' (O_2 , C- and N-sources) into de novo cell mass, CO_2 , and H_2O with assumed cell yield 0.4 g cell-C per g glucose-C:

Conditions	C-source	Oxygen	N-source	Cells	Carbon dioxide	Water	Acid-base disbalance
Glucose + NH_4Cl :	CH_2O	+ 0.593 O_2	+ 0.096 NH_4^+	$\rightarrow 0.4 \text{ CH}_{1.77}\text{O}_{0.49}\text{N}_{0.24} + 0.600$	CO_2	+ 0.790 H_2O	+ 0.096 H^+ + 0 OH^- (30)
Glucose + NaNO_3 :	CH_2O	+ 0.401 O_2	+ 0.096 NO_3^-	$\rightarrow 0.4 \text{ CH}_{1.77}\text{O}_{0.49}\text{N}_{0.24} + 0.600$	CO_2	+ 0.598 H_2O	+ 0 H^+ + 0.096 OH^- (31)
Glucose + urea:	CH_2O	+ 0.593 O_2	+ 0.048 CON_2H_4	$\rightarrow 0.4 \text{ CH}_{1.77}\text{O}_{0.49}\text{N}_{0.24} + 0.648$	CO_2	+ 0.742 H_2O	+ 0 H^+ + 0 OH^- (32)

To comply with the conservation conditions, these Eqs. (29)–(31) produce either H^+ (NH_4Cl as N-source) or OH^- (KNO_3 as N-source) that disturb the acid-base balance. The uptake of urea, an uncharged N-source, does not change the ionic status of cultural liquid, its only effect is slight stimulation of the CO_2 release.

The next interesting case is the complex protein-rich media of uncertain composition, which is the most popular type of media in laboratory practice. We selected the casein as a standardized commercial product with known elemental composition serving as a combined source of C- and N:

It turns out that casein is the strongest among the tested nutrient sources alkalization agent, nearly two times stronger than nitrate. Other widely used alkalization nutrients are the sodium and potassium salts of organic and amino acids.

The next biokinetic objective is the reconstruction of the pH time course in real batch culture or it could be the reconstruction of the auto-titration dynamics aimed at neutralizing metabolic acidification or alkalization. To fulfill this task, we need to specify not only the growth stoichiometry (Eqs. 30–32) but also the buffering capacity of cultural or environmental liquid, and to reconstruct the growth dynamics, expressed as a set of ODEs for cell biomass, nutrient substrates consumption and products formation. The

parameters required for coupling the growth of microorganisms with their degree of acid-base disbalance can be found again in Eqs. (30)–(32). For example, we can easily convert the cell ‘moles’ of these equations into the conventional dry weight of cell biomass and compare it with the moles of produced acidity or alkalinity. For example, the production of one gram of cells on glucose + NH_4Cl requires the cumulative use of 7.8 mmol of NaOH to neutralize the metabolic acidity. We can also state a stoichiometric yield-like parameter $Y_n = 7.8 \text{ mmol (g cell)}^{-1}$, stating that production of one gram of cell biomass causes metabolic acidification equivalent to release of 7.8 mmol of strong acid. Such data can be fruitfully used for the planning purposes, e.g., to calculate in advance the composition of nutrient medium (amount of energy, C- and N-sources, buffer molarity and respective buffering capacity) required for cultivation without instrumental pH control. Another more creative biotech solution would be to revise the medium composition in such a way that minimizes acid-base disbalance.

Effects of temperature

In chemical kinetics, the dependence of the reaction rate on temperature is explained by the Eyring transition-state theory. It is based on the use of thermodynamics and principles of quantum mechanics. The reaction proceeds through a continuum of energy states and must surpass the state of maximum energy when a transient activated complex is formed. Then, the dependence of the reaction rate constant k on the absolute temperature, T , is expressed as follows:

$$\frac{d \ln k}{dT} = \frac{\Delta H^* + RT}{RT^2} \quad (34)$$

where R is the gas constant and ΔH^* is the enthalpy of activated complex formation. The more popular Arrhenius equation is obtained by integration of Eq. (34) and a simplified substitution $\Delta H^* + RT \approx \Delta H = E_a$:

$$\ln k = \ln A - \frac{E_a}{RT} \quad \text{or} \quad k = Ae^{-E_a/RT} \quad (35)$$

where E_a is the activation energy and A is the integration constant, interpreted as the frequency of molecular collisions.

The Arrhenius equation fits well the biokinetic data under a narrow temperature range from zero to 20–60 °C as dependent on tolerance to the thermal denaturation (minimal in psychrophiles, maximal in thermophiles). Let us assume that denaturation is reversible with the equilibrium constant $K_T = [E']/[E]$, where E and E' stand for the active and denatured molecules respectively. Then, the combination of Eq. (35) with the van Hoff expression for K_T ($-RT \ln K_T = \Delta G^\circ = \Delta H^\circ - T\Delta S^\circ$) results in the following updated Arrhenius equation and its exponential approximation in Celsius temperature:

$$\mu_m = \frac{Ae^{-\frac{E_a}{RT}}}{1 + e^{\frac{\Delta S^\circ}{R} - \frac{\Delta H^\circ}{RT}}} = \frac{Ae^{-\frac{E_a}{RT}}}{1 + e^{B(1 - \frac{C}{T})}} \approx \frac{Ae^{\alpha T_c}}{1 + e^{B(1 - \frac{C}{273+T_c})}} \quad (36)$$

where ΔG° , ΔS° , and ΔH° are the standard Gibbs free energy, enthalpy, and entropy of the denaturation reaction, respectively, aggregated into constants B and C . In this equation, we made substitution of the reaction rate k for the maximum SGR.

The best experimental setup for verification and estimation of kinetic parameters is the exponential phase of the batch culture or turbidostat and pH-auxostat. The chemostat is not appropriate because of SGR dependence on two strong factors, temperature and limiting substrate concentration. In the case of soil incubation studies, soil community should have either continuous supply of nutrients, or experiments must be a short-term to avoid the effect of a hidden change of growth rate. In the example (Fig. 6), we measured the intensity of methane production by stabilized methanogenic community characterized by low SGR, that was continuously supplied by gaseous substrate (H_2 : CO_2).

Fig. 6 The effect of temperature on microbial activity in a methanogenic bioreactor (Panikov, unpublished). Experimental conditions: the *Sphagnum* peat core was continuously flushed with gas mixture N_2 : CO_2 : $\text{H}_2 = 90$:5:5 and off-gas mass-spectrometric recording of methane. After stabilizing at 3 °C for 2 days, the incubation temperature was programmed to rise linearly with the rate of 1.0 deg. C h^{-1} from 3 to 50 °C (panel A) or to cycle between 1 and 30 °C as shown by the red line (panel B insert). (A): The 10-min averaged CH_4 production rates plotted versus temperature fitted to Eq. (36). (B) The hysteresis in microbial response to temperature variation, red arrows indicate the temporal progression, and the insert shows the time series of temperature (red curve) and methane formation rate. Note different symbols (unfilled, grey, and black-filled circles) for three parts of the temperature gradient.

Within the biologically meaningful range of temperatures (0–60 °C), the exponential approximation does not deviate from the more accurate Arrhenius equation (Fig. 6A) but is more stable in solving the inverse problem. Contrary to chemical reactions, microorganisms demonstrate significant *hysteresis* in their response to cyclic temperature changes (Fig. 6B). In other words, the effect of temperature depends on how it varied in the past. It is explained by the fact that adaptation to temperature extremes (too cold, too warm) involves conditionally expressed macromolecules, e.g., the heat-shock proteins, desaturating enzymes, and chaperones (Strocchi et al., 2006). The SCM is capable of simulating the process after the update of Eq. (26): the r -variable should be multiple functions of s and T .

The special case of near-zero growth kinetics

Laboratory cultivation mainly occurs under an excess of nutrients with SGR close to the maximum, μ_m . In nature, microbial growth follows diverse patterns, remaining mostly continuous and very slow ($\mu \ll \mu_m$) because of severe nutrient limitations. Even in relatively rare *eutrophic* habitats, such as a plant rhizosphere or soil invertebrate gut, microorganisms divide no more than 1–2 times per day, while in *mesotrophic* and *oligotrophic* habitats (plant-free soil, subsoils, sediments) the doubling time can be months and years. Here we call such a low-intensity process a *near-zero growth* (NZG) and summarize below its specific features. Formally, any growth model, simple or structured gives a prediction of how microorganisms should react to extremely low s . According to the unstructured models, the maintenance term should play a crucial role: if we ignore the maintenance ($m = 0$ as in the original Monod model), the NZG is nothing more than a smooth growth deceleration ($\mu \rightarrow 0$ as $s \rightarrow 0$), however, if we accept the non-zero maintenance ($m > 0$, Eq. 9), then NZG is predicted to stop at certain threshold substrate concentration, $s^* = Y^m K_s m$, below which μ becomes negative implying net death of starving cells (Fig. 7B).

The laboratory reproduction of continuous NZG is a challenging problem. Batch culture at low starting substrate concentration (s_0) is not adequate because, at any s_0 producing a measurable amount of cells, the growth initially is inevitably too intensive and then abruptly stops and becomes negative after substrate depletion. In theory, a chemostat is a perfect option as the dilution rate, D , can be set at any level. However, the NZG range requires an unrealistically long stabilization period. For example, a chemostat culture would need to be operated uninterrupted for at least 4 to 5 months to establish a steady division frequency of once per month. Over this time period, there is a high probability of accidental equipment malfunction, wall growth, mutations, or contamination invalidating experimental results.

Fig. 7 Laboratory reproduction of the near-zero microbial growth (NZG) typical for soil environment (Panikov et al., 2015). (A) Schematic of continuous cultivation with cell retention (CCR). Medium is continuously delivered from the reservoir, while the outflow is passed through the tangential-flow filter, returning cells to the bioreactor. (B) The effect of the energy source concentration on microbial SGR. The non-structured Monod-Pirt model assuming a constant maintenance rate predicts cell death (negative μ) at $s < s^*$. The more advanced SCM model predicts an adjustable maintenance term allowing the positive NZG. (C) Experimental data on the NZG growth dynamics of *Pseudomonas putida* fitted to the SCM. (D) The hypothetical mechanism explaining the loss of reproductive capacity in the VBNC (viable-but-not-cultivable) cells caused by an uneven distribution of ribosomes during the cell division.

Continuous culture with cell retention (CCR) by using a dialysis membrane or tangential-flow filtration (Fig. 7A), provides a better practical alternative, bringing microbial cells to a monthly division frequency in only 1–2 weeks. The Monod chemostat model with constant positive m as applied to CCR (Eq. 9 combined with 19) predicts attaining of the so-called *state of maintenance*, the transition of microbial cells to the non-proliferating status ($\mu = 0$) preserving relatively high the maintenance catabolic activity. Such a hypothetical state has never been confirmed experimentally (Fig. 7). Instead, it was found (Panikov et al., 2015) that under chronic starvation in CCR, microorganisms undergo deep metabolic reconfiguration (about 40% of proteome replaced as compared with the cells grown at conventional SGR range). An immediate result of such adaptive changes was the progressive decrease of the maintenance term allowing a near linear increase of cell biomass concentration over time (Fig. 7C). The second conclusion was that a stable long-term NZG requires the differentiation of starving cells into growing and non-replicating VBNC (viable-but-not-nonculturable cells) forms, the latter preserving measurable catabolic activity. Over cultivation time, the proliferating cells eventually attain a steady state, their slow growth being balanced by VBNC production. Since growth deceleration is always accompanied by a dramatic decrease in the rRNA content, it was hypothesized that VBNC cells are produced because of asymmetry in the distribution of ribosomal particles between chronically starving mother and daughter cells (Fig. 7D). It is interesting that extremely slowly growing cells acquiring broad resistance to stresses other than starvation, including suboptimal temperature, toxic compounds, desiccation, and osmotic stress. Apart from the described *epigenetic changes*, there is a strong possibility of spontaneous mutations and selection of the GASP (Growth Advantage of Stationary Phase) phenotypes.

Concluding comments

The chapter introduces the basic terms, variables, and concepts established in microbiological growth kinetics. There is a wide range of models that present different degrees of perception of bioprocesses. It is a normal phenomenon, there is no perfectly correct model, and all of them including the simplest formulation could be helpful in scientific exploration provided their selection has been appropriately justified. The choice of biokinetic models should be based on available data and depends on the objectives of a particular study. Specifically, a soil scientist should estimate the degrees of involvement in a process of soil microorganisms and other soil biotas. We can envisage several situations:

- 1) The short-term (the time scale minutes-hours) response of the soil community to some specific factor. The process duration is too short to induce a measurable growth of soil microorganisms. In this case, the process kinetics should follow the equations listed in Table 1. It gives basic information about the kinetic order of reactions that could be very useful. Any growth models are not applicable.
- 2) The time scale of biomonitoring is extended to a few days, and there is a good chance of observing the initial growth of soil microorganisms but without deep changes in the community structure and accompanying deep shifts in environmental conditions. A typical example is soil incubation with easily degradable organic compounds, inducing intensive exponential growth. Such growth can be categorized as *simple biodynamics* with constant SGR and MMCC. Such growth can obey the simplest growth models (Monod, cell quota, logistic equation) or requires more advanced models (SCM, GEM) in the case of clearly expressed lag-phase indicating metabolic reconfiguration during the *complex biodynamics*.
- 3) The next step is the issue of *microbial heterogeneity*; how diverse the acting community is. If the studied bioprocess is carried out by a mixture of species with similar biokinetic characteristics, then the SCM could be still well appropriate to explore the dynamic patterns and help its better mechanistic understanding. Otherwise, researchers must address the multispecies interacting models. That topic will be touched on in the 2nd chapter of this series.

Abstract

The chapter summarizes the advance in microbial biokinetics aimed at the mechanistic understanding of soil biodynamics. The covered topics include methods to estimate microbial growth rates in nature, the origin of sustained soil fluctuations, navigation to the multitude of microbial habitats, the life strategy concept explaining the biokinetic diversity of soil microorganisms and the uncultivability phenomenon, decomposition kinetics of simple organic compounds, cellulose, and plant litter. The review specifies typical misconceptions and computational handicaps and gives recommendations on the correct account for the maintenance, seasonal microbial production, root exudation rates, and the organism-centered models of soil decomposition.

Key points

- The main challenge in the assessment of microbial growth rates in nature is that the apparent growth (the observed increase of cell number) could be only a small fraction of the true growth hidden by parallel elimination such as grazing by soil animals, lysis, active migration, or wash-out.
- Growth rate of microorganisms in soil and other natural habitats is essentially slower than in laboratory cultures because of non-optimal conditions, primarily nutrient deficiency
- There are few types of microbial habitats in the soil as dependent on nutrient supply, elimination of growing cells and the spatial assembly, these habitats support distinct dynamic pattern of microbial growth. The fastest growth rate is found in habitats with continuous nutrient supply and elimination (rhizosphere, digestive tract of soil animals), the slowest microbial growth is characteristic to the expanded dispersion zone with continuous and slow diffusional input of nutrients without biological elimination.
- The intensity of rhizodeposition as the main source of labile decomposable organic compounds (DOC) can be quantitatively defined using experimental ^{14}C pulse-chase data and the mechanistic kinetic model of the full chain of events: the photosynthetic uptake of CO_2 , Calvin cycle, phloem translocation, release of root exudates and their oxidative metabolism by the rhizomicrobial community. The earlier interpretation of the two-phase $^{14}\text{CO}_2$ evolution as a measure of microbial contribution is incorrect.
- Weekly (with period of 6–8 days) fluctuations of microbial biomass in the planted soils (in situ and in the plant-soil microcosms in climatic chambers) are induced by PPA and superimposed on the prey-predator cycles
- Diversity of biokinetic characteristic of soil microorganisms is explained by the Darwinian evolution under different circumstances of natural selection. We distinguish the products of r-selection (pioneer stages of succession), K-selection (climax communities), and L-selection (stressful environment), each of which has unique biokinetic and genomic characteristics. Modern growth kinetics reproduces the biodynamic patterns empirically observed in the opportunistic species (syn.: zymogenic and copiotrophic) as manifestation of the r-selection. The oligotrophic and autochthonous species are identified as the products of K-selection, and the extremophiles and stress-resistant species as the products of L-selection
- Substrate decomposition in soil does not follow the first-order degradation kinetics, the paradigm widely accepted since introduced by Jenny in 1941, because different plant litter C-pools are NOT degraded *independently* and *simultaneously* with the same rate over time, but *strongly interact* with each other (catabolic repression, inhibition, co-metabolism through ROS formation). Besides the degradation (depolymerization, oxidation) reactions are combined with the biosynthetic processes (growth of microbial decomposers and formation of their extracellular products). Instead, we suggest the organism-oriented decomposition model applied as a specific illustration to the process of cellulose decomposition.

Nomenclature

$D = F/V$	Chemostat dilution rate
DOC	Decomposable organic compounds
F	Medium feeding rate
K_s	Saturation constant defined as $K_s = s$ at $\mu = 0.5\mu_m$
m	Maintenance term, the fraction of catabolic rate that is not associated with growth
NZG	Near-zero growth under chronic starvation
ODE	Ordinary differential equation
p	Product concentration
PDE	Partial differential equation
PPA	Plant photosynthetic activity
$q_p = (1/x) \cdot dp/dt$	Specific product formation rate (SPR)
$q_s = (1/x) \cdot ds/dt$	Specific substrate uptake rate (SUR)
RE	Root exudation
ROS	Reactive oxygen species

s	Limiting nutrient substrate concentration, mostly DOC
SCM	Synthetic Chemostat Model
SGR	Specific growth rate
t	Time
V	Volume of cell culture kept constant in the chemostat
VBNC	Viable but nonculturable cells
x	Cell mass concentration
$Y = -dx/ds$	Cell yield per unit of consumed substrate
$Y_{x/p} = dx/dp$	Cell yield per unit of produced CO_2
$\mu = (1/x) \cdot dx/dt$	SGR calculation
μ_m	Maximum SGR, $\mu \rightarrow \mu_m$ as $s \rightarrow \infty$

Introduction

The first chapter of this series on microbial kinetics outlined the general biokinetic terms, principles, and models. Here our objective is to demonstrate some applications of the described biokinetic approach to soil microbiology. Soil is commonly recognized as an especially tough research object for microbial ecologists. Because of its solid state and opaqueness, soils do not allow direct non-destructive microscopy, flow cytometry, or even a uniform distribution of soluble reactants (e.g., ^3H -thymidine to measure the DNA replication rates) without artefactual distortion of the native structure. Further, any soil is a mosaic of multiple microbial microhabitats, a single soil crumb may be the home of organisms with dramatically different tolerance limits and metabolic types (aerobic-anaerobic, autotroph-heterotroph, prototroph-auxotroph, etc.), each in its own tiny niche that differs chemically or physically from other niches. It makes the soil microbial community especially diverse, accounting for up to one-quarter of Earth's diversity. Most (70–90%) soil prokaryotes are elusive not-yet-culturable species known only from their genomic signatures; this intriguing biokinetic puzzle presents both challenges and opportunities to learn previously unknown molecular principles, and their discovery could impact the entire modern biology.

There are many other not-yet-explained biokinetic features observed in soil, e.g., the periodic fluctuations of microbial activity, soil microbiostasis, poorly understood declines in microbial decomposition rates resulting in paludification and litter accumulation in some soils, and the catastrophic decline of soil organic matter in other soils. For centuries, soil biologists fruitlessly try to estimate the intensity of root exudation as a main source of easily decomposable organic matter and explain the coexistence of the fast- and slow-growing species violating the law of competitive exclusion. These and many other intriguing questions belong to the area of biokinetics, a scientific discipline dealing with the rates and mechanisms of biological processes, an approach combining precise measurement of dynamic variables with mechanistic mathematical modeling.

Soil biokinetic studies were started in 1940–50 focusing on the decomposition (Jenny, 1941), nitrification (Saunders and Bazin, 1973), denitrification (Smith, 1980), and the rhizosphere effect (Newman and Watson, 1977). The initially slow development of soil biokinetics was dramatically accelerated by the International Biological Program (IBP, 1964–1974) aimed to explore global biological productivity as a basis of human welfare. The ecological term *productivity* is synonymous with the biokinetic term *growth rates* addressing the previously ignored dynamic status of natural populations. The IBP demonstrated that microbial ecology lagged far behind the other ecological subdisciplines dealing with plants and animals, and the gap has been quickly filled due to the energetic efforts of several research teams discussed below. The second even more significant impact was produced by the Global Change agenda that made soil biology part of modern biospheric interdisciplinary science. It became imperative to provide quantitative information on the soil resources, C-pools, and fluxes of the greenhouse gases from the soil to the atmosphere. In addition to fluxes and pools, soil biologists were charged with the task of deciphering the native regulatory mechanisms involved in the ongoing climatic changes to be included in the predictive biospheric models and development of the mitigation strategy. The third accelerating factor was the proteogenomic revolution in biology affecting environmental research. It provided powerful molecular tools, generating reliable phylogenetic data on the soil community composition and offered the opportunity to follow the population dynamics of individual taxonomic units and selected taxonomic groups.

This chapter starts with the basic biokinetic question: how to measure the rates of microbial growth in soils and how fast soil microorganisms grow? It is not a trivial task, and to evaluate the true growth rate of microbial populations, we often need to reveal hidden sources and sinks for growing microorganisms. The next issue addressed is the previously mentioned multitude of soil microhabitats. We show how to find a way through this labyrinth and systematize the observations into the space of permissible combinations. Each element of this system has respective analogs in laboratory cultivation opening the way for purposeful modeling and selection of correct growth models. The third part of this article addresses the issues of the biokinetic diversity of soil microorganisms that evolved under different circumstances of natural selection. It answers one of the puzzling ecological paradoxes: why the fast- and slow-growing populations competing for the same nutrient resources do co-exist in nature, apparently violating the law of competitive exclusion. The introduced concept of multiple life strategies explains the paradox and sheds the light on the nature of uncultivability phenomena. Finally, the wealth of accumulated knowledge is applied to the core problem of soil biology, the kinetics of organic matter decomposition.

Estimation of microbial growth rates in nature

Any kinetic study critically depends on the quality of the primary experimental data including the measured rates of a process. Microbiological kinetics is no exception. Unfortunately, the accurate estimation of microbial growth rate in nature is not a trivial task even in the postgenomic era. Thank to culture-independent molecular techniques (such as metagenomic and metatranscriptomic analyses, FISH, SIP, oligonucleotide probes) soil microbiologists now can resolve the taxonomic structure of the whole soil community, its active part, or a subset of species responsible for a given soil process. It is also possible to monitor the changes in the microbial biomass or cell numbers over time $x(t)$. However, it is not enough to answer the question about the growth rates. Let us see where the problem lies by looking at one specific case.

Understanding true vs apparent growth rates

Suppose, our task is to assess the growth performance of bacterial strains intended to use as soil ameliorants. We start by recording the growth curves $x(t)$ of all strains using a plate reader with shaking and temperature controls. Growth is automatically recorded as an increase of optical density (OD) at 600 nm every 5 min. At the end of the experiment, the recorded data are exported to Excel, and SGR for each strain is found by numeric differentiation applying the Excel function SLOPE and AVERAGE for three consecutive OD points vs time:

$$\text{SGR} = \frac{1}{x} \frac{dx}{dt} \approx \frac{1}{\text{AVERAGE}(\text{OD}_1 : \text{OD}_3)} \times \text{SLOPE}(\text{OD}_1 : \text{OD}_3, t_1 : t_3) \quad (1)$$

Let us assume that we found the best candidate strain (short lag phase and high SGR), and want to test its long-term stability using continuous culture with medium feeding rate F , ml h^{-1} and culture volume V , ml. Again, we measure OD in periodically withdrawn samples of bacterial suspension and calculate the SGR, but now the mathematical expression is different:

$$\text{SGR} = \frac{1}{x} \frac{dx}{dt} + D, D = \frac{F}{V} \quad (2)$$

In 1–2 days of cultivation, the derivative dx/dt of Eq. (2) becomes very small and eventually disappeared when the culture attained a steady state when $dx/dt = 0$ and $\text{SGR} = D$. Now we can formulate the principal challenge faced by microbial ecologists exploring growth kinetics in nature: how to distinguish the *apparent* growth rates dx/dt from the *true* rates such as the sum of two terms in Eq. (2), one of which is hidden from the observer. In laboratory experiments, it is not a problem because we design our own experiments. However, the natural growth patterns could remain enigmatic. Over the past several decades, microbial ecologists made some progress in resolving the outlined problem. There are no one-size-fits-all solutions, rather we have a collection of successful procedures that we can group into three clusters: **group B** (from the Batch) applicable to the simple growth regimes without hidden sinks when the apparent growth rate is a true estimate; **group C** (from the Continuous) applicable to a steady-state continuous growth when growth is balanced by the elimination; and finally, **group U** (from Uniform) of the uniformly applicable methods for any growth regime but having other restrictions.

On-site direct microscopy

Regular glass slides (Staley, 1971) or specially designed *artificial substrates*, such as rectangular capillaries (Perfil'ev and Gabe, 1969) were installed at the field sites (ponds, wetlands, submerged soils) to track the colonization and following growth by native microbial populations. The compound phase-contrast microscopes were available nearby or permanently immersed in water (Staley, 1971). Interestingly, it was found that *Chlorella* cells grew without division during the day, and divided into four daughter cells at night. Occasionally this cycle was interrupted, with no cell division until the second night. This technique requires exceptional microscopic skills and patience (James Staley was one of such high-rank professionals) and cannot be recommended for wide use. It is also limited to clean aquatic habitats and is selective to the relatively large cells adherable to the glass surface. Today underwater microscopy is supported by a specialized video-recording hardware (Mullen et al., 2016). Potentially, the Staley approach can be upgraded today to the automated surveillance system based on the multiple microfluidic devices permanently installed in a pond, fen, or saturated soil. Research diving will be not required, and video recording of the growth dynamics can be transmitted via optical fiber. Thus, on-site microscopy has a good chance to provide exceptionally valuable data on division frequency, responses to fluctuating environments, and other autecological features of native populations. The described approach is qualified as a B group, and any immigration and emigration or other elimination events must be accounted for.

Methods based on the analysis of the cell-division cycle

In eukaryotes, the mitotic cells can be recognized morphologically, and the time of mitosis (TM) is constant, although the total cell cycle duration (equivalent to the generation time $g = \ln 2/\mu$) varies. In prokaryotes, the equivalent of TM , the nearly constant part of the cell cycle, starts with the formation of division septa and ends with the separation of daughter cells. TM must be established for a specified eukaryotic microorganism (fungi, algae, protozoa, slime mold) in preliminary experiments with pure cultures. To find the

generation time g , a researcher needs to perform a direct microscopic examination of the environmental sample and count the total number of the targeted organism (N) and the number of mitotic cells (N^*). Then the generation time g is found as

$$g = \frac{TM}{R} \text{ or } g = \frac{TM}{1.44R}, R = \frac{N^*}{N} \quad (3)$$

where 1.44 is empirical correction factor (Brock, 1971). As applied to the prokaryotes, the FDC (Frequency of Dividing Cells) method is not restricted to a selected taxon, instead, it was suggested that the method be calibrated using the enriched chemostat culture of bacteria from the studied habitat (Hagström et al., 1979). The method belongs to the U-group, as in theory it does not depend on a hidden microbial sink. There are several drawbacks, the most essential computational inconsistency being Eq. (3), which implicitly assumes that the native population is not synchronized and, as a result, the fraction R remains constant over time. However, this assumption contradicts the observations on the nocturnal division event in *Chlorella* (Staley, 1971). Another drawback is that the critical parameter TM must be known and based on the ex situ culturing. Therefore, this technique is applicable to only known culturable species. First, many native microorganisms cannot be cultivated. Second, even well-known organisms are not easily distinguishable without FISH, immunofluorescent staining, or other advanced microscopic methods. It does make sense, to apply this approach to relatively simple synthetic or native communities, e.g., the rumen, hydroponic plant culture, mycorrhiza of well-studied plants, and soil-plant inoculation experiments including the application of mycorrhiza-infected roots.

Nonreplicating genetic markers

Two such markers have been tested: (i) superinfecting mutants of phages that enter the cells of the pathogenic strain of *Salmonella typhimurium* but do not replicate (Meynell, 1959) and (ii) ^3H -thymidine labeling of bacteria after label removal (Brock, 1971). In both cases, the labeled cells are mixed with the unlabeled indigenous populations. At each cell division, the fraction of the population which contains the label is halved, therefore, the doubling time can be calculated from the rate of marker dilution. Computationally, the isotopic dilution is equivalent to the elimination term D in Eq. (2) if we use as a dynamic variable the concentration of labeled cells $x^*(t)$, therefore it belongs to the C-category. In practice, this approach can be applied only to a limited number of genetically explored species and to very simple communities or single-species studies, such as infected organs of animals. Specific drawbacks: a, the accuracy of SGR estimation drops dramatically over time parallel to the label dilution, and b, the method is based on assumption that the biokinetic qualities of the labeled and the native cells are identical, but the labeling procedure involves laboratory cultivation that significantly affects the phenotype. In any case, the approach played a historically important role (Meynell, 1959): for the first time, it demonstrated a dramatic decline in bacterial growth rates in vivo as compared with laboratory cultivation. *S. typhimurium* dividing in nutrient broth every 30 min after intravenous inoculation into a mouse grew 20 times slower!

Approaches developed for steady-state populations

Here we outline three techniques that belong to the C-type and are designed to measure the normally hidden elimination factors playing the same role as cells washout in continuous culture.

Water streams

Some natural habitats have a visible similarity with the continuous cultivation of cells like chemostats. Moreover, the volume replacement rate equivalent to dilution rate D is often easier to measure than SGR. The classic example is the hot-spring drain ways as a habitat of thermophilic algae (Brock, 1971). The technique involved the measurement of the algal washout rate after growth was stopped by darkening the system with a wide non-transparent screen. The following exponential decrease of $x(t)$ in the effluent stream was monitored to calculate the dilution rate equal numerically to SGR under normal illumination. It was found to be 0.4 d^{-1} ($g = 40 \text{ h}$).

Digestive track of invertebrates

The soil-related example is the digestive systems of the earthworms, isopods, millipedes, and other widely spread in nature invertebrates that continuously consume detritus (e.g., plant litter) converting the ingested matter into excrements highly enriched with microorganisms. Assuming the chemostat-type bioprocess for animals with a short gut (isopods), we can estimate the growth rate of microbial commensals as:

$$\text{SGR} = D \frac{(x_{\text{out}} - x_{\text{in}})}{x_{\text{out}}} \quad (4)$$

where x_{in} is microbial biomass content in the animal feed, x_{out} is the enlarged biomass in fresh excrements. Here D is an equivalent of the dilution rate in a chemostat found experimentally as $D = 1/TT$, the reciprocal of the food transient time TT , how long it takes for ingested food to travel from an animal's mouth to anus. Parameter TT is measured by feeding the animal with stained plant litter or soil labeled with inert visible particles, e.g., silicone beads, see below the difference between TT and half-decay time.

Stopping microbial grazing

In many natural environments including soils, the main elimination factor for growing microbial cells is their grazing by protozoa, microarthropods, nematodes, and other small animals. This elimination rate cannot be measured directly as in method described under *Water streams*. Instead, the microbivores are removed by filtration, based on the solid fact that even the smallest predators are bigger than bacteria. In marine and freshwaters ecosystems, bacterial cells have a size of 1–3 μm and do not form multicellular colonies or flocks, hence filtrations through 5- μm filters allow efficient removal of the protozoa and metazoan predators without major disturbance of bacterial populations. Then the temporal turbidity increase versus unfiltered control is a good measure of their true growth rate in situ. This approach must be used with care since filtration can reduce the nutrient flux produced by large photosynthetic organisms including algae.

Isotope incorporation techniques

Heterotrophic CO_2 fixation

Dark $^{14}\text{CO}_2$ fixation rate was suggested as a measure of the total heterotrophic bacterial production (Romanenko, 1964). The carboxylation of pyruvate produces oxalacetate, it is one of several *anaplerotic* metabolic reactions, serving to refill the intermediates of the TCA cycle used for the biosynthetic processes. In theory, the stoichiometry of anaplerotic reactions should be tightly coupled with the overall cell growth. However, the experimental data display a wide range of 0.01–0.12 between the fixed CO_2 and the total assimilated C, most probably because of the multitude of alternative metabolic pathways. Thus, it is advisable to establish the conversion factor for a given soil and for specific conditions in preliminary incubation experiments. The method is very sensitive and robust for diverse environments including soils. It can be used as a non-destructive way to introduce the label (^{13}C or ^{14}C) through the soil aeration pores to practically any metabolically active soil chemotrophic organisms for following molecular studies, such as SIP. Phototrophic organisms can also consume the label under light exposure. The last case no longer belongs to the heterotrophic category, it is the autotrophic CO_2 fixation rate with a simpler 1:1 stoichiometry, i.e., $\text{SUR} = \text{SGR}$, the uptake rate is equivalent to the growth rate if the biomass $x(t)$ is consumed substrate is expressed in the same C-units, e.g., mg C cm^{-3} .

DNA synthesis rate

Another popular method is the measurement of the uptake rate of labeled precursors of nucleic acids, thymidine (DNA), uridine (RNA), and adenine (both macromolecules) (Karl, 1980). The use of isotopes with high specific activity guarantees minimal alterations of the in-situ growth conditions. At the same time, the amount of added nucleoside should be large enough to suppress their synthesis *de novo* from endogenous cell compounds. The main deficiency of this technique, as applied to soil, is an uneven distribution of precursors within the soil mass. Typically, nucleosides are added as a buffered solution making a soil slurry, which can dramatically affect the growth rates of soil microorganisms. Another problem is the ambiguity of conversion factors from a nucleoside uptake rate to a microbial growth rate. Also, the resulting SGR could be overestimated because of nucleoside utilization as a C source.

Protein synthesis rate

Similar to the previous method, but using labeled leucine instead of thymidine to estimate the SGR from the rate of label incorporation into cellular proteins.

All these isotope methods are sensitive enough to reduce the incubation time down to a few minutes (which must be extended to a few hours in extreme and poor environments, e.g., the polar, and hypersaline waters, permafrost, etc.), they measure the instant biosynthetic activity of environmental cells, and results are not affected by the parallel slower elimination processes. Therefore, the isotope methods belong to the U-category and can be applied to any taxonomic or metabolic type of microorganisms. There are no restrictions in applying all three subcategories to homogeneous habitats (fresh and marine waters, wastewater treatment, rumen). However, soils and other heterogeneous habitats cannot be uniformly mixed with labeled biosynthetic precursors (see above comment about DNA synthesis rate) without at least partial disturbance, but the heterotrophic CO_2 fixation method is the most universally applicable.

Respiration rate

The respiration intensity can be estimated from the rates of dissolved oxygen consumption (the most appropriate in aquatic habitats) or CO_2 formation in terrestrial environments, including soils. CO_2 can be recorded with an infra-red gas analyzer (IRGA), portable mass spectrometers, and other analyzers, either in situ with soil chambers or in laboratory incubation experiments with undisturbed soil cores or homogenized sieved and substrate-amended soil samples. In the field and plant-soil microcosm studies, the crucial problem is to distinguish microbial versus plant root respiration, the topic was exhaustively reviewed by Kuzyakov and Larionova (2005). If root respiration is successfully resolved, then the total respiration rate (RR), expressed as $\text{mg CO}_2\text{-C (h kg soil)}^{-1}$ can be used to calculate the average SGR of heterotrophic soil microorganisms:

$$SGR = \mu = Y_{x/p} \frac{RR}{x_{soil}} \quad (5)$$

where x_{soil} is an independently measured total biomass of respiring soil microorganisms, mg cell-C (g soil)⁻¹, and $Y_{x/p}$ is the cell yield per mass unit of produced CO₂. Microbial growth limited by the energy and C-sources is not accompanied by a noticeable release of products other than CO₂, therefore growth C-balance is very simple:

$$\begin{array}{ccccc} \text{Consumed substrate} & & \text{Produced cells} & & \text{Produced CO}_2 \\ \Delta s - C & = & \Delta x - C & + & \Delta p - C \end{array} \quad (6)$$

Dividing both parts of Eq. (6) by $\Delta x - C$, we have

$$\frac{1}{Y} = 1 + \frac{1}{Y_{x/p}} \text{ or } Y_{x/p} = \frac{Y}{1 - Y} \quad (7)$$

where Y is the conventional yield factor expressed as g cell-C/g substrate-C. For most heterotrophic microorganisms Y varies between 0.5 and 0.6 g C (g C)⁻¹ (Payne, 1970) implying an $Y_{x/p}$ range 1.0–1.5. It can be more accurately determined in preliminary soil incubation experiments under specified conditions (see below). The main advantages of this method are (i), well-established instrumental techniques for monitoring CO₂ emission from soils to the atmosphere at different footprints from a closed chamber covering a fraction of m² to the Eddy covariance flux towers with footprints 10³–10⁴ m²; (ii) a central role of respiration in the metabolism of any organism and its well-predicted stoichiometry (Payne, 1970); (iii) availability of the CO₂ fluxes data for the entire biosphere like FLUXNET that makes possible to generate microbial productivity patterns in seasonal and year-to-year dynamics without dedicated experimental efforts. The limitations: (a) significant deviations from a simple stoichiometry (Eq. 6) under anoxic conditions (should be added specified fermentation products to Eq. (6)) and under deficiency of mineral nutrients (additional products, mostly the polycarbonic acids); (b) complexity of the measured CO₂ fluxes that are not equivalent to the RR, being affected by the transient processes at the soil-atmosphere boundary, e.g., the temperature inversions; (c) possible contribution of the abiotic decarboxylation reactions and release of the trapped CO₂ especially significant in soils with low biological activity.

There are other microbial processes associated with gas exchange, e.g., methanogenesis (uptake of H₂ and CO₂, formation of CH₄), methane consumption (uptake of CH₄, release of CO₂), denitrification (formation of N₂, NO, and N₂O), CO and H₂ consumption by the carboxydobacteria and the hydrogen bacteria, etc. Growth rates of microbial populations responsible for the listed processes can be also estimated using equations similar but not identical to Eq. (5): the total microbial biomass x_{soil} and the yield factor $Y_{x/p}$ must be updated for a respective physiological group of soil microorganisms; fortunately, it can be done relatively easy in a preliminary calibration (Panikov and Sizova, 1996).

Microbial productivity inferred from periodic fluctuations of soil biodynamics

First observation and the IBP renaissance

More than 100 years ago, a team of protozoologists led by Ward Cutler at the Rothamsted Experimental Station performed one of the most scrupulous soil studies (Cutler et al., 1923): every day at 10 am for 365 (!) consecutive days, they undertook a full taxonomic survey of soil protozoa with a differential count of the active and dormant (tolerant to 2% HCl forms as well as the total bacterial count by plating one soil dilution 4×10^{-6} on mannitol-asparagine-mineral agar. They made two important observations for us: (i) a statistically significant correlation with time delays between the protozoan and bacterial counts characteristic for the prey-predator interactive system, two amoebae were recognized as the most active soil microbivores; and (ii) a remarkably sustained periodic fluctuation in the numbers of bacteria and protozoa with periods 4–8 days that were not related to environmental factors. Such fluctuations would not be detected with a less regular sampling schedule.

After 40 years, the same high-frequency sampling was continued as a systematic soil biodynamic study across the East European Plain and Siberia from polar deserts to subtropics. It was a part of the IBP with the goal of estimating microbial growth rates in diverse terrestrial ecosystems. The plating was replaced by the direct count of bacteria stained by erythrosine. The periodicity of bacterial fluctuations was confirmed but not for all soils, the highest amplitudes were found in the tundra, where the count could rise in a few days by more than three orders of magnitude, up to 1500 times (Parinkina, 1973). Moving to lower latitudes, from tundra to taiga, deciduous forest, and steppe, fluctuation amplitude progressively declined, and no fluctuations were detected in semi-desert soils (Aristovskaya, 1974).

The original interpretation of microbial periodicity, calculation of SGR, and deficiencies of the method

It was hypothesized that, apart from the predator-prey interactions, the fluctuations were caused by the periodic accumulation in the soil of some unknown autoinhibiting metabolites susceptible to spontaneous oxidation or volatilization, e.g., H₂, ethylene oxide, a hypothetical compound *periodine* (Aristovskaya, 1974). The overall production of the fluctuating bacterial growth was calculated as follows: the bacterial abundance curve over time, $x(t)$ was split into the fragments separated by the local extremes $x_i^{\max}$ and $x_i^{\min}$, then the bacterial production was calculated as a sum of all positive increments, $\Delta x_i = x_i^{\max} - x_i^{\min}$. Each negative increment was interpreted as cells consumed by predators and was either added to the total (Aristovskaya, 1974) or ignored, resulting in a two-times smaller bacterial production (Parinkina, 1973). The generation time, g , was found to vary from 7 to 100 h, surprisingly intensive growth as compared with other published results. We will show below that this calculation was not correct.

The described approach was not widely accepted as a technique to estimate SGR. It misses fungi and actinobacteria, the mycelial organisms whose abundancies cannot be expressed in cell numbers. The procedure is too laborious, cumbersome, and destructive to the field site because of extensive soil coring (humorously called 'Swiss cheese syndrome'). Another discouragement stems from the stochastic nature of soil fluctuations, they rarely look like regular *oscillations*, rather the distinct rises and drops sooner or later become a random scatter. There were also doubts about the authenticity of the phenomenon since the observed variations of bacterial count over time $x(t)$ could be interpreted as a result of the x variation across the space, the different bacterial numbers in the replicate soil samples. The most radical criticism was the logical argument denying the mere possibility of the discussed phenomenon based on the following reasoning: an observable periodicity requires a global growth synchronization of soil microorganisms, but it is impossible in a mosaic soil environment because bacterial cells occupying separated soil microsites *a priori* should not communicate with each other. Such extreme nihilism is not fair as we show below. Periodicity patterns may be not the best primary data to estimate SGR, but they do exist as a biodynamic phenomenon that deserved to be thoroughly explored for a better understanding of soil ecology.

Contemporary view on periodic fluctuations

All doubts about the authenticity were adequately addressed by complementing the manual and destructive procedure of bacterial count with other techniques including the instrumental non-destructive recording of gas emission. Fluctuations of the expected duration of 4–8 days were established for CO₂ emission rates and soil gas profiles using the permanently installed membrane gas probes and the collars of the gas flux chambers with removable tops (Panikov and Gorbenko, 1992; Panikov et al., 2007). Even more accurate recording of the diurnal and day-to-day variation of gas exchange dynamics was achieved in the laboratory plant-soil microcosms kept in climatic chambers with artificial illumination (Panikov, 1995). On the other hand, periodic fluctuations were never found in the unplanted soil, indicating the essential role of plants as inducers of soil fluctuations. It was also confirmed by the time-series statistical (harmonic and cluster) analyses of the field experiment (Panikov and Gorbenko, 1992). It revealed that every rise in the fluctuating soil biodynamics started with increasing of the plant photosynthetic activity (PPA) followed by the delayed response of soil microorganisms (soil respiration, increased bacterial count), and then even more delayed protozoan activation.

Contrary to the earlier hypotheses explaining microbial fluctuations by the internal soil factors, the plant-centered concept does allow for *synchronization* of microbial activity throughout the soil mosaic because the plant roots and associated mycorrhiza penetrate the entire soil layer reaching most of the microbial microhabitats and combine them into an integrated cross-communication system. Diurnal cycles of PPA and root exudation force rhizosphere bacteria to divide synchronously roughly once a day in the rhizosphere. Day-to-day variations in rhizodeposition can affect microbial activity in two ways, by changing the concentration of decomposable organic compounds (DOC) and the number of soil microsites within the zone of plants influence.

Last question, what causes the PPA of plants to fluctuate? A fully competent answer should be given in the future based on interdisciplinary research crossing the borders of plant and soil biology. The known facts primarily based on the CO₂ fluxes can be summarized as follows: (i) fluctuations occur either outdoors or indoors; (ii) the fluxes are synchronized across the geographical scale well above the ecosystem or landscape levels (Fig. 1); (iii) variable environmental conditions (moisture, temperature, illumination) affect the flux intensity but not the *periodicity* of fluctuations. Thus, a *master* oscillator is likely to be of an extraterrestrial radiation nature, such as *solar wind*. Curiously, the atmospheric chemistry data (von Savigny et al., 2019) has a clear signature of the 27-day Sun rotation cycle, and it produces subharmonics remarkably similar to soil fluctuations.

What is wrong with the original calculation of SGR and how to correct it?

The original method of calculation (Aristovskaya, 1974; Parinkina, 1973) is based on intuition and is not accurate. To find the true SGR, we simulated the fluctuating growth using the following mathematical model:

$$\text{Plant – derived DOC – pool, } s \quad \frac{ds}{dt} = F - q_s x; F = A \left(B + \pi \frac{t}{T} \right); q_s = \frac{Q_s s}{K_s + s} \quad (8)$$

$$\text{Microbial biomass, } x \quad \frac{dx}{dt} = \mu x - q_x z; \mu = Y q_s; q_x = \frac{Q_x (x - x_0)}{K_x + x - x_0} \quad (9)$$

$$\text{Protozoa, } z \quad \frac{dz}{dt} = \eta z - a_z z; \eta = Y' q_x \quad (10)$$

$$\text{CO}_2, p \quad \frac{dp}{dt} = (1 - Y) q_s x + (1 - Y') q_x z + a_z z - D \left(\frac{p}{\Theta} - c_0 \right) \quad (11)$$

$$\text{The sum of all variables} \quad \frac{ds}{dt} + \frac{dx}{dt} + \frac{dz}{dt} + \frac{dp}{dt} = F - D \left(\frac{p}{\Theta} - c_0 \right) \quad (12)$$

The DOC are generated by the plants through the process of rhizodeposition, F , proportional to PPA (green curve in Fig. 2). DOC are consumed by microorganisms producing new cell mass and CO₂, and microbial cells are eliminated by protozoa. The sum of four variables, s , x , z , and p close the C-balance, so Eq. (12) is used for the verification based on the conservation law. The diurnal variations are neglected for clarity but the day-to-day variations are simulated using the sine function (Eq. (8), F depends on time,

Moscow, 55.75° N 37.62° E

Pushchino, 54.94° N 37.35° E

Fig. 1 Example of the soil biodynamics synchronization at the geographical scale. CO₂ emission from soil was simultaneously recorded at two field sites 100 km apart. The shaded areas mark two synchronous emission peaks (Panikov and Gorbenko, 1992).

Fig. 2 Simulation of the periodic soil fluctuations and demonstration of the way to reconstruct the SGR dynamics based on the observed amplitude and frequency of fluctuations.

A and B are the constants, and T is the period). θ stands for the soil air-filled porosity, required to define the concentration gradient between soil CO_2 , p , and the atmospheric CO_2 concentration, c_0 .

Simulation results (Fig. 2, left column) show the idealized fluctuation patterns that are not always observed in nature but other essential features (growth intensities, time delays, CO_2 emission, soil biomass) do agree with the published field observation (Panikov and Gorbenko, 1992). The right column compares the former intuitive and the correct ways of calculating microbial productivity: the top panel shows results for bacteria and the bottom panel shows similar curves for protozoa. The primary observation data collected in the field are the bacterial $x(t)$ and protozoan count $z(t)$. Normally it is obtained daily but we use for clarity the smaller time step of one min to produce a continuous curve. The former intuitive calculation is shown as gray curves; for clarity, the positive increments $\Delta x_i/\Delta t_i$ are also presented with the 1 min temporal resolution as of the positive derivatives $dx(t)/dt$ and $dz(t)/dt$. The perfectly correct productivity of bacteria $\mu(t) \cdot x(t)$ and protozoa $\eta(t) \cdot z(t)$ was obtained from numeric integration and plotted as continuous black curves. We see that intuition fails badly. Two variants (with and without adding the negative terms Δx_i) gave respectively 15- and 30-times underestimated bacterial and 5-times underestimated protozoan productivity vs correct results. The reason is a wrong instinctive assumption that bacteria are not grazed over periods when Δx_i are positive and do not grow when Δx_i are negative. The truth is that fluctuations never stop the growth of either bacteria or their grazers, rather their growth rates vary in response to the fluctuating environmental conditions. In fact, bacterial SGR depends on soil temperature and moisture and on available DOC and does not depend on the density of grazers or the rate of elimination. Another curious correction result is that the true SGR of soil bacteria fluctuates between 0.7 and 0.27 day^{-1} equivalent to the division frequency once per day and per 2.5 days respectively. The same SGR is found for microbivores. Another wrong intuitive expectation is that the microbial generation time should match the fluctuation period. The soil weekly periodicity is completely independent of bacterial division frequency contrary to the diurnal cycles (see observation on *Chlorella* (Staley, 1971)): bacteria divide once per day when DOC reaches maximum, the next division happens in 2 or 3 days. Note that the discussed relatively high growth intensity is limited to the rhizosphere and the top soil enriched with DOC, rather than to the entire soil community.

How to fix the problem of the SGR calculation based on weekly fluctuations? Is it possible to recalculate the published data? Yes, the problem can be fully resolved but only if there are both sets of primary data, $x(t)$ and $z(t)$. The first practical step is the smoothing of the time series using splines followed by numeric differentiation to obtain the apparent rates dx/dt and dz/dt , both steps can be completed with regular Excel. Then we add to both derivatives the hidden parts of the growth mass balance (marked below in red):

$$\text{Protozoan productivity} \quad \eta(t) \cdot z(t) = Y' q_z z = \frac{dz}{dt} + a_z z \quad (13)$$

$$\text{Bacterial productivity} \quad \mu(t) \cdot x(t) = Y q_s x = \frac{dx}{dt} + \frac{1}{Y} \left(\frac{dz}{dt} + a_z z \right) \quad (14)$$

Eqs. (13) and (14) are obtained by rearranging Eqs. (9) and (10) respectively. The correction is simpler for protozoa, it is just a mortality term. For bacteria, the hidden production part is the consumed microbial mass required to produce the total mass of microbivores including the dyed part. Fig. 2, the right column presents the corrected results as filled circles, and as we see, the circles perfectly match the continuous curve indicating that two independent computing ways produce the same results. Correction success critically depends on the selection of two parameters, Y' and a_z , which can be borrowed from the published sources (Curds and Cockburn, 1968) or adjusted using computing procedures minimizing simulation error (Excel users are encouraged to implement the Solver add-in). The count of bacteria alone without grazing data (or other elimination processes) is not sufficient for adequate correction.

Seasonal decomposition of organic matter

Principle of the method and its deficiencies

As in measurements based on respiration rate, this approach is based on growth stoichiometry (Eq. 6), the only difference is that the term $\Delta p\text{-C}$ (produced CO_2) is replaced by $\Delta s\text{-C}$ (consumed substrate). Rearrangement of Eqs. (6) and (7) gives the following equivalent of Eq. (5):

$$\text{SGR} = \mu = Y \frac{\text{SUR}}{x_{\text{soil}}} \quad (15)$$

where SUR stands for substrate uptake rate. As most soil microorganisms are decomposers, SUR is equivalent to the round-year average *soil decomposition rate*. Eqs. (5) and (15) look similar but as a source of primary observational data SUR is not defined as clearly as RR. In addition, the CO_2 determination is done instantly with high precision and accuracy using well-developed instrumental procedures. However, soil decomposition is a process studied for centuries but still poorly quantified because of its natural complexity (see below). It is a gigantic matrix of biotic and abiotic, catabolic, and biosynthetic reactions, thousands of reactants, products, and regulatory factors. Some recalcitrant DOC components have turnover times of up to decades and centuries, some are degraded in hours, and some remain unknown. To summarize, seasonal decomposition cannot be recommended as an experimental protocol but it can be useful as a computational experiment for establishing the upper limit for microbial productivity allowed by the C-balance of an ecosystem. For this purpose, it has been implemented in several studies of diverse ecosystems (see references in Panikov, 1995) revealing rather slow growth of soil microorganisms with generation time from 10 to 100 days and sometimes producing absurd results of negative SGR. Below we discuss three sources of computational inconsistencies and suggest relevant corrections.

Correction for the overstated maintenance requirements

The meaning of the maintenance term, m - the non-productive uptake of catabolic substrates - is clear but its direct measurement is impossible. Instead, it is found indirectly as a deviation from the proportionality between the catabolic substrates uptake rate, q_s , and the SGR, μ :

$$\mu = Yq_s = Y^m(q_s - m) \quad (16)$$

$$Y = Y^m \frac{q_s - m}{q_s} \quad (17)$$

where Y^m is the constant standing for the substrate-to-biomass conversion efficiency under imaginary condition $m = 0$. Classic growth kinetics assumes the m -term to be a constant, and it is indeed acceptable for a narrow SGR range from μ_m down to $\sim 0.1\mu_m$. But under deep nutrient limitation ($\mu \ll \mu_m$), cells undergo adaptive metabolic reconfigurations, remarkably reducing their maintenance requirements. Soil modelers in their growth equations occasionally predicting the negative SGR make two mistakes: (i) apply inadequate growth models with a constant m -term ignoring the adaptive self-adjustment of cellular catabolic machinery, and (ii) borrow from published sources the maintenance coefficient m in combination with the apparent yield Y rather than Y^m , making a 'double charge' because the Y -values already account for the maintenance. Both mistakes can be fixed by using more advanced and fortunately relatively simple kinetic models like SCM (see Section "Decomposition kinetics").

Correction for cryptic microbial growth

Cryptic growth refers to hidden microbial growth as a cannibalistic reutilization of the microbial necromass. For example, the depleted batch culture displays a net decline in total cell biomass, but some cells remain viable and continue an invisible slow growth by utilizing the necromass and the autolytic products of other cells. Most soil models ignore cryptic growth (Table 1, Eq. 18), assuming that microbial cells grown on the plant-derived DOC mysteriously disappear with the rate constant k_1 rather than stay in the soil and further participate in the soil C-cycle.

More realistic options for the grown cells are: (i) to stay in the soil and continue the DOC consumption; (ii) enter the dormancy state, (iii) be killed by parasites (phages, Bdellovibrio, etc.) or consumed by microbivores to produce the exploiter's biomass, CO_2 and the excretory or lysis products refilling the DOC-pool, (iv) be transformed into stable humus-like compounds with a long turnover time. For the climax soil community at a quasi-steady state, option (i) is accounted for simply by removing a meaningless rate constant k_1 leading to nowhere; we also neglect (ii) and (iv) based on the reasoning that transition to dormancy is compensated by germination, and humification is balanced by humus degradation. So, the only pathway to be considered is iii) as shown in the second graph and translated to the second more realistic set of ODEs. Eqs. (19), (20), and (21) give three improved estimations of microbial productivity respectively for microbial decomposers, for microbivores, and for their sum. Note, that we combine predation and parasitism into one elimination factor. Bacteriophages already attracted the attention of microbial ecologists as a strong factor impacting soil microorganisms. However, adequate biokinetic data on their lytic and lysogenic cycles are sparse. To economize on words, we refer to protozoa as the most active bacterial predator. The common opinion is that soil fungi are consumed mostly by nematodes, and both groups (bacteria and fungi) are eliminated to different degrees by microarthropods, viruses, and bacterial Bdellovibrio-like parasites.

As expected, the highest production is predicted by Eq. (21) simply because it sums up two trophic groups. Interestingly, with $Y=Y' \geq 0.5$, the cumulative microbial production exceeds the primary DOC input, and this conclusion does not contradict the mass conservation law. As a matter of fact, growth with recycling occurs as a multistep process likely involving a succession of species. Each step obeys the first and second laws of thermodynamics, with some consumed energy being dissipated. Eq. (19) for soil microorganisms alone also predicts their production exceeding the input F under conditions that $Y \geq 0.66$ at a fixed $Y' = 0.5$. Both

Table 1 Mathematical expressions designed for estimation of microbial productivity in soils.

Graph	Mass-balance ODEs	Productivity	
	$\dot{S} = F - q_s X$ $\dot{X} = Y(q_s - m)X - k_1 X = \mu X - k_1 X$ $\dot{P} = (1 - Y)q_s X - k_D P$	$\mu X = Y(F - mX)$	18

Red arrows indicate the external inputs or outputs fluxes to the microbial compartment. The variables: S, the decomposable substrates; X, microorganisms; Z, microbivore protozoa; N, necromass and excretory products. The symbols over arrows stand for: PP, the fraction of the primary production filling the DOC-pool, μ and η are the SGR of respectively soil microorganisms and predators, k_1 and k_2 are the rate constants for respectively death of protozoa and conversion of necromass to the DOC-pool.

yield factors are still within the published range for the bacteria (Payne, 1970) and protozoa (Curds and Cockburn, 1968). The reutilization has a modest impact on predator production (Eq. 20) because these organisms are assumed to be unable to grow cryptically on the lytic products, and a minor positive impact of reutilization is due to the consumption of the cryptically grown prey.

Prospects for correction of the underestimated DOC input to soil

The improved expressions (19)–(21) can still substantially underestimate microbial productivity if we use the wrong input parameter F . The conservative estimate of F is often limited to the seasonal formation of plant litter, which varies from 50 to 150 g m⁻² in the tundra to 2500 g m⁻² in the virgin steppe (Panikov, 1995). These estimates are not accurate and could be misleading if we take the recalcitrant plant necromass as the only DOC source. A more abundant and accessible nutrient source is the **rhizodeposition**, which includes 3–23% of the particulate matter (the sloughing-off border cells, mucilage, and dead root hair), while the bulk 77–97% belongs to the soluble pool of *root exudates* (RE), a mixture of sugars, amino acids, polycarbonic acids and soluble proteins and polysaccharides with MW 10–50 kD (Warembourg and Billes, 1979; Nguyen, 2009). Rhizodeposition has been studied for centuries, and still is actively discussed in contemporary periodicals. Unfortunately, the data on rates of RE remains controversial. The review by Cheng and Gershenson (2007) lists five approaches to estimate the C-fluxes in the rhizosphere: (i) direct chemical analyses of the hydroponic solutions, (ii) ¹⁴CO₂ pulse-chase, (iii) continuous labeling, (iv) natural isotope abundance, and (v) reporter genes. The conclusion is that each approach has drawbacks and none is fully satisfactory. The impediments arise from the vulnerability and biocomplexity of roots, their irregular architecture, tight binding to the soil, and close association with mycorrhiza and prokaryotic cells. There is also the kinetic handicap of an unknown sink (e.g., the produced RE are immediately consumed by microbial commensals) that we discussed from the very start (see above) and that can be resolved by a combination of experimental studies with mechanistic modeling. Below we demonstrate this strategy as applied to the most popular and the most controversial pulse-chase method.

Resolving interpretive and computational controversies of the ¹⁴CO₂ pulse-chase method

Pulse-chase method (Fig. 3) involves a short-term (down to 20 min) exposure of the aboveground plant to the ¹⁴CO₂, the following 2–4 days the relocation of ¹⁴C is evaluated within the plant and in the rhizosphere. The technique was warmly accepted as a simpler and faster option than continuous labeling. Especially encouraging was the finding that the ¹⁴C that passed through the plant was recovered as a consequence of two phases in ¹⁴CO₂ evolution from the root (Fig. 3F), the first peak was attributed to root respiration (RR), and the second to rhizomicrobial respiration (RMR). The conclusion was supported by the fact that plant sterilization removed the 2nd phase (Warembourg, 1975; Warembourg and Billes, 1979). But soon other researchers (Todorovic et al., 2001) presented a high-quality continuous record of ¹⁴CO₂ demonstrating that plant sterilization does not remove the second peak (Fig. 3I). The case is still not closed, some supporters of the succession concept split the ¹⁴CO₂ output into RR and MR parts irrespective of the peak number (Fig. 3H), it is called *the C-flow model* but it looks more like an empirical curve fitting satisfying the condition that RMR is close to RR ignoring any mechanistic details (Domanski et al., 2001; Kuzyakov and Larionova, 2005).

To resolve the conflict of opinions, we suggest here a minimal kinetic model of the soil-plant system (Fig. 3A–C) that mimics the known mechanisms: fixation of ¹⁴CO₂ in the chloroplasts (Calvin cycle), movement of the ¹⁴C-sap (sucrose and other photoassimilates) downward from leaves to roots through the phloem according to the commonly recognized **pressure flow hypothesis** (Knoblauch et al., 2016), utilization of ¹⁴C sap for the plant cells growth and dark respiration, and, finally, exudation of the ¹⁴C sap near root tips and its consumption by the rhizobacteria controlled by the protozoan grazers. The crucial issue is the spatial distribution of ¹⁴C: should we picture the pulse movement in a plant like a **plug flow** (no mixing of the moving liquid elements across the phloem pipe) or a mixing flow such as a series of stirred vessels after adding a color tracer (Fig. 3C). Truth is somewhere between these two extremes, but we select the second option based on the following reasoning. The arrows (Fig. 3A) indicate possible points of the ¹⁴C entries to the plant's leaves during the labeling step (green arrows), followed by the entries of ¹⁴C-sap into the phloem (blue arrows) and finally the exudation steps (black arrows). All these entries are multiple points evenly distributed across the vertical ordinate. There could be a **random distribution** of ¹⁴C at the microscopic scale but there are no chances for the **macroscopic spatial gradients** of ¹⁴C associated with plug flow which requires PDEs to explore the combined effect of **time and space**. Thus, a pulse labeling protocol produces a cloud of ¹⁴C intermediates in the aboveground (AG) compartment, resulting in the extended entry of ¹⁴C to the belowground (BG) compartment. The BG traffic further increases the randomness of the ¹⁴C distribution because of the irregular geometry of the root's phloem: the long and wide segments provide a fast downward ¹⁴C movement while the short and narrow pipes support mostly a slow lateral movement. The following set of ODEs represents the after-pulse ¹⁴C flows:

Aboveground

$$^{14}\text{CO}_2 \quad \frac{dp_1}{dt} = -q_p \gamma_1, \quad (22)$$

$$^{14}\text{C} - \text{sap, photoassimilates} \quad \frac{ds_1}{dt} = q_p \gamma_1 - q_s \gamma_1 - TR s_1 \quad (23)$$

$$^{14}\text{C} - \text{phytomass (shoots)} \quad \frac{dy_1}{dt} = Y_1 q_s \gamma_1 - k_1 \gamma_1 \quad (24)$$

Fig. 3 Kinetic exploration of the pulse-chase technique to quantify root exudation (RE): (A) Cartoon illustrating relationship between RE and water flow based on the Münch hypothesis. (B) Model's flowchart. (C) A simplified analog of the pulse chase: a constant water flow through two vessel one with leaky bottom. A red dye is a tracer analogous to the $^{14}\text{CO}_2$ pulse. (D) Example of the sensitivity analysis: the tracer washout dynamics in the AG (blue curves) and BG compartment (orange) as dependent on their volumes. The V1:V2 ratio is a crucial factor affecting the tracer profile. (E) The effect of diurnal cycles on the washout profile. (F) and (G). Experimental data (Warembourg and Billes, 1979) on $^{14}\text{CO}_2$ release rate (F) and ^{14}C concentration in solution (G). (H) A non-recommended way to differentiate the roots and microbial respiration, data redrawn from (Kuzakov and Larionova, 2005). (I) A continuous high resolution recording of $^{14}\text{CO}_2$ (Todorovic et al., 2001). The shaded rectangles in (E) through (I) panels indicate the dark periods.

Belowground

$$^{14}\text{C} - \text{sap, photoassimilates} \quad \frac{ds_2}{dt} = TR s_1 - q_s y_2 - \psi s_2 \quad (25)$$

$$^{14}\text{C} - \text{phytomass (roots)} \quad \frac{dy_2}{dt} = Y_2 q_s y_2 - k_2 y_2 \quad (26)$$

$$^{14}\text{CO}_2 \quad \frac{dp_2}{dt} = (1 - Y_2) q_s y_2 + (1 - Y') q_x z + (1 - Y) q_m x - D p_2 \quad (27)$$

$$^{14}\text{C} - \text{root exudates} \quad \frac{dm}{dt} = \psi s_2 - q_m x + k_z z \quad (28)$$

$$^{14}\text{C} - \text{Microbial biomass} \quad \frac{dx}{dt} = Y q_m x - q_x z \quad (29)$$

$$^{14}\text{C} - \text{Protozoan biomass} \quad \frac{dz}{dt} = Y' q_x z - k_z z \quad (30)$$

where, q stands for specific uptake rates, subscripts p , s , m , and x indicating uptake of CO_2 , sap, RE, and bacterial cells respectively; Y , Y_1 , Y_2 and Y' are the growth yield of microorganisms, plant shoots, roots, and protozoa respectively; k_1 , k_2 , and k_z are the mortality rates for plant shoots, roots, and protozoa respectively; ψ is the exudation rate.

Fig. 3C pictures a simplified hydrological analog of the plant system for easier understanding of the pulse-chase technique. There are two stirred vessels analogous to AG and BG compartments with continuous water flow mimicking the phloem translocation. At time zero, a red tracer is added to the first vessel as the equivalent of a $^{14}\text{CO}_2$ pulse. Finally, to mimic the root exudation, the second vessel is assumed of having a leaky bottom, the lost liquid being collected in a tub and pumped back to imitate the rhizobacterial uptake (the dotted line). What are the conclusions from this allegory? *First*, it is a reminder that the system is driven by the unlabeled feeding of CO_2 , the decline of the ^{14}C is primarily caused by its washout (= dilution with ^{12}C) in the same way as the color tracer is washed out by the continuously running clear water. It is the ^{12}C flow that causes exponential decay of radioactivity observed in all experiments (Fig. 3F, H, and I) rather than sequential processing through RR and RMR discussed in publications. *Second*, the leakage (an analog of RE) cannot be detected from the washout profile, to assess the leakage, we must record the volume collected in the tub below, therefore recording of the extraradical ^{14}C is absolutely required as suggested by Kuzyakov and Siniakina (2001). *Third*, the only useful information to be extracted from the washout profile, is the turnover rate, TR , an equivalent of the dilution rate in chemostat $TR=D=F/V$. Not too much, but as applied to plants, it allows estimation of the hard-to-measure phloem translocation flux as a product $TR \times \text{sap pool}$. The sap pool is a measurable variable, but not a phloem volumetric flow, so the washout profile provides important information. Further discussion of TR is given below.

Some processes are slow (^{14}C -phytomass) and can be assumed to be constant during the pulse-chase experiment, while others are so fast (respiratory oxidation of ^{14}C -sap) that can be simplified to the steady-state variables to be found from the zeroed ODEs. Between these two extremes is the phloem translocation having the intermediate characteristic time (Eqs. 23 and 25) that defines the pace of the entire process. Fig. 3D shows solutions of these equations simulating the ^{14}C -sap profile as dependent on the AG-to-BG sizes ratio, some of these curves fit the experimentally recorded $^{14}\text{CO}_2$ evolution rates (Fig. 3F, H, and I) indicating high probabilities that the full model would reproduce the pulse-chase process. The next simulation (Fig. 3E) sheds the light on the nature of the observed bimodal shape of the $^{14}\text{CO}_2$ emission. Two or more interruptions are associated with the diurnal cycles, specifically with slowing the phloem traffic in dark periods with the possible additional impact of the plant dark respiration.

What about the RE? Is it possible to estimate the exudation rates based on the pulse-chase principle? Yes, it is possible, and there is a clear signature of RE in the first pulse-chase experiments performed 44 years ago (Warembourg and Billes, 1979). It is a mostly ignored extraradical pool of ^{14}C compounds in the nutrient solution (Fig. 3G). *First*, the release of ^{14}C from roots started after the latent period of 10–12 h required for ^{14}C -sap to reach the root tips, exuded, and metabolized by microorganisms. The published data on the speed of translocation varies (Knoblauch et al., 2016) and the observed delay is within the range. *Second*, the authors overlooked a very important difference in the behavior of native vs sterilized plants, the native system displayed ^{14}C fluctuations as a characteristic pray-predator pattern (Fig. 2). This pattern was undeniably destroyed by sterilization. These two observations confirm that RE does exist and plays an important role in the ^{14}C budget. To convert the extraradical ^{14}C -pool size into the exudation flux, one needs to fit the whole set of Eq. (22)–(30) to the experimental data set. Unfortunately, the paper of Warembourg and Billes (1979) does not contain all the required information.

To summarize, the pulse-chase technique can be fruitfully used for the estimation of RE. The minimum set of required data includes (i) the CO_2 exchange fluxes separately for the AG and BG compartments and (ii) the BG extraradical pool of the soluble organic compounds. The measurements (i) and (ii) must be duplicated for ^{14}C and the total $^{12}\text{C} + ^{14}\text{C}$ isotopes before and after the pulse to estimate the specific radioactivity and express the obtained results using conventional mass units, e.g., the exudation fluxes expressed as $\text{mg C (kg soil h)}^{-1}$ or $\text{g C m}^{-2} \text{ h}^{-1}$. It is more reasonable to express rhizodeposition and RE as a part of the gross PPA because it is the only origin of RE. Units such as %, mmol, or mg C per plant or per g of the root are meaningless. It is also highly desirable: a, to monitor continuously the fluxes using data logging to a computer rather than manually collecting CO_2 with the alkaline trap; b, to have a record of microbial (bacteria, fungi) populations; and c, to have a record of microbial predator (protozoa, nematodes). The protozoa and nematodes are always present in rhizospheres of laboratory-grown plants or in situ. The hydroponic

and aeroponic plant cultures are no exception. It sounds paradoxical, but the account of microbial elimination is an absolutely required element of the realistic mass-balance and kinetic models dealing with the chemistry of the soil-plant systems. Finally, the two-phase succession concept and the associated deconvolution procedure illustrated by Fig. 3 H must be recognized as a hypothesis that failed to pass the experimental verification. It is a normal event in science, nothing personal!

Diversity of soil microhabitats

Principle of habitats classification

Usually, the soil is viewed as a mosaic of diverse microbial habitats representing independent microsites that are unique in many characteristics. They can be drastically dissimilar in the amount and qualities of growth substrates, aeration level, texture, moisture, etc. However, there are just a few general features, which determine the *population dynamics* of microorganisms in any microsite. We list below three such features:

1. **Substrate input** that can be continuous (1) or discontinuous (2). In the first case, the input flux of nutrient compounds can vary over time but remains non-zero because its microbial uptake is compensated by substrate delivery from some external source. The discontinuous pattern implies rare occasional pulses of nutrients without refill that result in short-term explosive growth followed by a period of complete starvation.
2. Grown cells can be **retained** within a habitat (α) or **eliminated** (β). Examples of microbial elimination include cell washout, grazing by protozoa, nematodes, and other soil animals, lysis by parasites (phages, *Bdellovibrio*), and the active migration of microorganisms between different soil habitats. Migration occurs through (i) flagellar motion across the soil water-filled channels (motile bacteria and zoospores), (ii) sliding, gliding, and twitching of bacteria devoid of flagella (*Mycobacterium*, *Myxococcus*, *Flavobacterium*, *Cytophaga*), and (iii) through the vectorized apical growth of soil fungi, actinobacteria, and other mycelial organisms. The last migration style is the most efficient in a heterogeneous soil environment, it can proceed across any soil pore space including those filled with air and organo-mineral gel-like matter rather than only the water-filled voids accessible to the motile cells.
3. Habitats vary in **spatial assembly**, being either (a) homogeneous or (b) heterogeneous. In the first type of habitat, all variables (cells, nutrient substrates, and products) are distributed evenly or randomly across the space (like we found in the pulse-chase labeling of rhizodeposition, see above). In the second type of habitat, we observe the spatial gradients of the biokinetic variables (x , s , p) essential from the biokinetic perspective for the understanding of how microbial growth is controlled. The homogenization factors in arable soils include irrigation, plowing, harrowing and other forms of tillage, the explorative activity of the fossorial soil animals. Soil homogeneity is never as perfect as in the stirred bioreactor or even natural water. Close to true homogeneity can be established through the air-filled soil pores for the volatile and gaseous nutrient substrates.

Three independent ordination axes produce eight possible combinations (Table 2), and two of them are logically forbidden because any kind of spatial gradients of growth substrates implies the *continuous* rather than *discontinuous* delivery of nutrients.

Representing examples

Fig. 4 depicts several characteristic microbial habitats occurring in the soil. The most extensive and extremely oligotrophic soil habitats belong to the category of *dispersion zone* (1a β); this zone embraces the root-free parts of the soil profile and the underlying subsoil that do not receive seasonal input of fresh plant litter or any other plant-derived DOC. Numerous microbial populations inhabiting these habitats grow very slowly on volatile or soluble mobile compounds, which continuously diffuse from richer soil parts. The diffusion flux is extremely small as most of the nutrients are intercepted by other microorganisms residing closer to the source. Examples of such remote sources of mobile compounds are (i) the poorly aerated anoxic soil layers harboring anaerobic microbial communities that produce diverse fermentation products including gases (H_2 , CH_4) and volatile aliphatic compounds (formic, acetic, and propionic acids, alcohols, ketones, and aldehydes); (ii) rhizosphere soil and (iii) the top organic soil layer with fresh plant litter discussed below. Some microorganisms in the dispersion zone are chemolithotrophs using inorganic compounds as energy sources: H_2 , H_2S , S, Fe^{2+} , Mn^{2+} , etc.

Table 2 Matrix of growth patterns in situ and ex situ (Panikov, 1995).

Spatial assembly	Substrate input			
	Continuous (1)		Discontinuous (2)	
	Cell removed (α)	Cell retained (β)	Cell removed (α)	Cell retained (β)
Homogeneous (a)	1a α	1a β	2a α	2a β
Heterogeneous (b)	1b α	1b β	Forbidden	Forbidden

Fig. 4 Some microbial habitats in nature.

The greatest intensity and mostly uninterrupted microbial activity are localized in the topsoil under the *plant litter* layer, *rhizosphere*, and *digestive tract* of soil animals (habitats of the types 1aβ - 1bβ). The C-substrates for microbial populations are the monomeric labile compounds (sugars, aliphatic, and aromatic organic acids) derived from plants either as root exudation in the rhizosphere or released by extracellular hydrolytic enzymes from the lignocellulose, hemicellulose, pectin, and other polymers of dead plant matter. The belowground plant necromass (root litter and root sloughing) provides microbial C-substrates in the rhizosphere. Root exudation is proportional to the PPA and, therefore, follows a diurnal pattern with mid-day maximum and nocturnal decline. The process of plant litter decomposition is more monotonous, being under the control of the activity of the hydrolytic microorganisms and their extracellular enzymes. Spatially, all these habitats are rather heterogeneous; however, the simpler non-distributed models of homogeneous growth kinetic are often justified because of random variation of cell mass and other variables (rather than clearly expressed spatial gradients) combined with the macroscopic scale of experimental data.

Clear vertical gradients are formed in the litter layer from uncolonized fresh plant debris on the top to the highly decomposed sublayer at the interface with mineral soil. At the microscale, the spatial heterogeneity of microbial colonies (mainly fungi and some actinobacteria) is manifested as their differentiation into growing extension zone and non-growing reproductive compartments (Fig. 5). Within the rhizosphere, there are also several spatial gradients of different scales: (a) the vertical gradient of the photosynthate from green aboveground part of plants to the roots, (b) the horizontal gradient between distant trees or tussocks and the bare soil, and (c) the micro-scale gradient around root hair with the maximal concentration of microbial cells and substrates on the root surface (rhizoplane) and exponential decline outwards.

Soil millipedes, isopods, some earthworms, and other soil animals representing the *primary decomposers* inhabit the litter layer and feed on plant debris. The ingested lignocellulose material is mechanically disrupted by the mandible, moistened with saliva, and then passed to the midgut and then to the hindgut. The digestive tract of various soil invertebrates harbors not only specific symbionts but also the normal free-living microorganisms occurring in soil or plant litter, e.g., *Pseudomonas*, *Flavobacterium*, *Vibrio*, *Enterobacter*, *Streptomyces*. The acceleration of their growth in the hindgut is due to favorable conditions: neutral pH, optimal moisture, elevated concentrations of nutrient and growth factors (amino acids, peptides, vitamins) as well as the continuous input of fresh substrate and concomitant removal of digestion products (glucose) to prevent the catabolic repression slowing down biodegradation of plant polymers. Due to peristaltic motion, the content of the gut is mixed and homogeneous. *Secondary decomposers* (i.e., the earthworm *Allolobophora chlorotica*) pass soil mass containing bacterial cells and fungal mycelia through their digestive track; they digest some microorganisms while other resistant species thrive in the gut accelerating their growth.

Fig. 5 Mechanisms of colonial growth. (A) microcolonies of bacteria, and fungal mycelium observed in the soil. (B) bacterial growth on the agar surface. (C) fungal growth on agar. Note that bacterial cells colonized the surface of gel consuming nutrients diffusing from the underlying agar layer. The mycelial organisms can spread inside the agar layer and colonize the space faster independent of nutrient diffusion. Under closer examination, we can see a similarity between growing mycelial colony and chemostat. On both systems, the growth pattern is (a) continuous, (b) steady-state, and (c) substrate-limited. The role of the bioreactor in the fungal colony plays the leading front called the peripheral zone of a colony; the non-growing core of the colony is equivalent to the product bottle, while the pump is substituted by the outward growth of the colony invading the non-yet occupied gel volume.

Discontinuous, explosive microbial growth occurs within the decomposition *hot spots* initiated by relatively rare events of input to the soil of the large amounts of easily degradable organic compounds ($2a\alpha - 2a\beta$), such as feces and carcasses of animals, rain washing of mobile organic compounds from plant foliage, manure particles, dry-rewet or freeze-thaw cycles releasing soluble C, etc. Intensive microbial growth tends to attract predators and parasites and therefore is accompanied by the elimination of produced microbial biomass but only after the latent period required for a build-up of microbial biomass.

Growth dynamics in various habitats

Microbial growth expressed as a time series of microbial biomass, x , and the limiting substrate concentration, s , in any type of habitats is described by the following mass balance equations:

$$\begin{array}{cccccc} \text{Net change} & \text{Input} & \text{Loss} & \text{Growth} & \text{Maintenance} & \\ \frac{ds}{dt} & = & F(t) & - & G(s) & - & \frac{\mu x}{Y} & - & mx \end{array} \quad (31)$$

$$\begin{array}{cccccc} \text{Net change} & \text{Immigration} & \text{Elimination} & \text{Growth} & \\ \frac{dx}{dt} & = & V(t) & - & H(x) & + & \mu(s)x \end{array} \quad (32)$$

To specify kinetic expressions, we can rely on kinetic models developed for the laboratory cultivation system by selecting the closest analog to the respective natural habitat (Table 3). For example, the growth of soil bacteria in the intestine of earthworms is

Table 3 Examples of typical natural habitats as their counterparts in laboratory cultivation systems.

Type	Lab cultivation system	Soil habitats		
		Location	Substrate input	Elimination factor
1a α	Chemostat, auxostat	Rhizosphere	Rhizodeposition: exudation and sloughing	Predation by protozoa and nematodes, phagolysis, environmental stresses
1a β	Fed batch culture, dialysis culture	Dispersion zone	Diffusion of gases, volatile and soluble OM	Death from stress factors. Grazing is not operational at low prey density
1b α	Plug-flow culture	Digestion tract of invertebrates	Predigested plant litter	Digestion and washout with feces
1b α	Colonies on agar, solid-phase fermentation	Plant litter	Litter fall, root sloughing	Predation by microarthropods, apical hyphal extension
1b β	Column packed with microbial biofilms	Soil water channels	Trickling solutions	Cell motility
2a β	Simple batch	Temporal decomposition hot-spots without grazers	Occasional release of DOC	Starvation death after DOC depletion

remarkably similar to the tubular (plug-flow) reactor. The rhizosphere community can be viewed as the continuous growth of microorganisms in the chemostat or the phased culture with the fluctuating input of the limiting C-substrate synchronized with diurnal photosynthetic cycle and rhizodeposition (see above review on soil periodic fluctuations). Slow microbial growth in the dispersion zone is adequately simulated by dialysis culture, and the growth of fungi degrading plant litter has many common kinetic features with colonies developing on agar.

Growth models based on the SCM for various homogeneous cultivation systems are shown in Table 4. The listed cultivation protocols reproduce a wide range of microbial physiological states that potentially occur in situ. Fig. 5 illustrates additionally the

Table 4 The major cultivation systems relevant to the purposes of microbial ecology.

Cultivation	Design	Equations of mass balance	Growth Dynamics
Chemostat		$\frac{ds}{dt} = D(s_r - s) - q_s x$ $\frac{dx}{dt} = \mu x - D x, \mu = Y(q_s - m)$ $\frac{dr}{dt} = \mu \left(\frac{s}{K_r + s} - r \right)$ $F, V, D=F/V, \text{ and } s_r \text{ are constant}$	33 
Batch		As the Eq. (33) at $D = 0$ The initial conditions: at time zero, $x = x_0$ (inoculation dose of microbial cells), and $s = s_0$, initial substrate concentration	
Phased culture (repetitive batch cycles with washout)		As the Eq. (33) with s_r following a square wave pattern (input pulses at regular time intervals): $s_r = \begin{cases} >0, & \text{if } t = \tau n \\ 0, & \text{if } t \neq \tau n, n = 1, 2, \dots, n \end{cases}$ where n is the number of cycles of duration τ h.	
Continuous dialysis, the shortest way to reproduce NZG		There is no cell washout, $-Dx = 0$. The absolute growth rate A is constant, while SGR progressively declines: $\frac{dx}{dt} = A = YF(s_r - s_m) = \mu x;$ $\mu = \frac{A}{x_0 + At}$	34 
Fed-batch culture, another way to reproduce NZG		Parameter D progressively declines: $D = \frac{F}{V_0 + Ft}$ Note the similarity with the dialysis culture: the total cell mass in the bioreactor, Vx , increases linearly over time.	35

Cultivation	Design	Equations of mass balance	Growth Dynamics
A tubular or plug-flow continuous culture that produces steady state batch growth at any phase		$\frac{\partial s}{\partial t} + f \frac{\partial s}{\partial z} = D_s \frac{\partial^2 s}{\partial z^2} - q_s x, f = \frac{F}{A}$ $\frac{\partial x}{\partial t} + f \frac{\partial x}{\partial z} = D_x \frac{\partial^2 x}{\partial z^2} - \mu(s)x \quad [14a]$ where D_s and D_x are diffusion coefficients, A is the cross-section area. Note that the right side of Eq. (27) is the <i>along-the flow-growth rate</i>. At low D_x and D_s, the tubular culture reproduces the batch process unrolled over space, z, instead of time, t	

Based on Panikov NS (1995) *Microbial Growth Kinetics*. Springer Netherlands.

colonial growth, which is predominantly used as a preparatory step (isolation, purity test, etc.) but can be also performed in a precise quantitative à la bioreactor fashion. One of the best criteria of adequacy of the selected cultivation system to mimic the natural state of microbial population is the growth intensity expressed as SGR. If the ex situ and in situ values coincide, then the cultivation technique may be regarded as ecologically adequate.

Diversity of growth characteristics. Life strategy concept

Explanation of the concept

Jacque Monod once wrote that “anything that is true of *E. coli* must be true of elephants, except more so”. He was probably right as far as the basics of molecular biology are concerned, but NOT about behavioral stereotypes. Growth kinetics was mostly studied using *E. coli* and several other model bacteria (*Aerobacter aerogenes*, *Bacillus subtilis*, *Pseudomonas putida*, *Mycobacterium smegmatis*) as well as yeasts (e.g., *Saccharomyces cerevisiae*, *Pichia pastoris*). It is a tiny fraction of microbial diversity but large enough to convince us that the dynamic behavior of different microorganisms is remarkably different even if they use the same or similar spectrum of nutrients. Some grow fast others slowly; some are highly resistant to an adverse environment while others are vulnerable. Surprisingly, the natural biokinetic diversity remains sustainable, slow, and vulnerable populations coexist with fast and resistant individuals rather than being eliminated as dictated by the famous Gause’s law of competitive exclusion. One explanation of the paradox is just *spatial-temporal inhomogeneity* of natural habitats: potential competitors grow as separate colonies in distant loci of soils without strong direct interactions, and temporal (seasonal, weekly, or diurnal) fluctuations further neutralize individual advantages and disadvantages within a diverse community. However, there is another more important and often neglected factor of sustained species diversity: the pressure of natural selection varies under specific circumstances in such a way that competitive advantage not always is given to the fastest or the most resistant species. Fig. 5 illustrates a survival triad, three axes of ordination (could be more) showing the competitive advantage of organisms relative to each other: to invade free ecological space or promptly recover after devastating perturbation (*r*-axis); the ability to compete for limited resources in a stable but overcrowded community (*K*-axis), and survive under unfavorable environmental conditions (*L*-axis). Respectively one can distinguish the following three extreme types of natural selection which correspond to three types of life strategy.

- (1) **r-Selection.** The symbol *r* stands for apparent growth rate, the difference $\mu - a$ between the true growth rate and the mortality rates in the logistic equation (Panikov, 2023, Eq. 17, Part 1) it defines the start of the logistic growth curve. Respectively, *r*-selection operates on the pioneer stages of successions typically caused by perturbations, such as a forest fire that kills most of the organisms in a mature ecosystem. Nutrients are temporary in excess, therefore *r*-selection acts in favor of the opportunistic organisms, the *jackal* type of strategy, a kind of ‘first come, first served.’
- (2) **K-Selection.** The parameter *K* of the logistic equation stands for the carrying capacity of the ecosystem, the maximum biomass that could be attained at available resources. Fluctuations of biomass *x* around *K*, determine the state of mature ecosystems saturated by organisms under stable environmental conditions. Respectively, *K*-selection acts in favor of highly competitive species, the ‘lions’ type of life strategy.
- (3) **L-selection.** The symbol *L* is not shown explicitly in the logistic equation, but it plays the role of a hidden parameter indicating the minimum abundance that provides sustainable existence in a natural community. The condition $x < L$ stands that the population is very close to extinction. The *L*-selection operates under adverse environmental conditions caused by various stresses: starvation, too cold or too hot, extreme pH, desiccation, intoxication, etc. The products of *L*-selection mostly fluctuate around *L*-level unable to withstand competition with stronger *r*- and *K*-selected species under favorable conditions and survive mostly due to raised resistance to stresses. It is the ‘camel’ type of life strategy.

How the survival triangle is constructed?

We start from field observations or lab competition experiments with mixed cultures, in which we follow time series of two and more competitors (up to 10–20, if we use appropriate barcode markers to distinguish individual strains). The second option is much easier and less ambiguous. Different circumstances of natural selection are provided by using respective cultivation methods shown in Table 5. The r-selection is simulated using the exponential phase of simple batch culture (none of the nutrients yet depleted), while K-selection is reproduced in one of the substrate-limited continuous cultivations, e.g., chemostat at reasonable low D , fed-batch, or dialysis cultures. Finally, L-selection can be simulated by exposing growing mixed cultures to continuous or pulsed adverse growth conditions, e.g., suboptimal pH, temperature, oxygen level, etc. The pulsed exposure is performed as a temporal departure from optimum with the following periods of recovery that gives a more realistic pattern of the combined L/r-selection operating in most soils from tropics to tundra. Continuous exposure is a more appropriate choice for lab reconstruction of the permanently pessimal soil environments, e.g., the arid and polar deserts, hot springs, salt marshes, etc.

As a simplified illustration, let us consider competition between three species shown in Fig. 6: *Pseudomonas fluorescens* (P), *Arthrobacter globiformis* (A), and *Caulobacter crescentus* (C). The exponential growth in the batch culture (r-selection), the outcome of the competition was as follows: P (the winner) > A (midway) > C (the weakest competitor). The principal kinetic predictor of competition is the maximum SGR, μ_m : 0.45 (P), 0.25 (A), and 0.15 h^{-1} (C). The same three bacteria have completely different competitive strengths under K-selection reproduced in the mixed glucose-limited dialysis culture: $C > A > P$ with C as an evident winner. The most informative predictors were the substrate saturation constants (K_s 5.0, 1.0, and $0.3 \mu\text{M}$ for P, A, and C respectively) as well as more parsimonious growth stoichiometry of C and A with higher yields and lower maintenance term, m as compared with P. Results of described competition in the batch and dialysis cultures are plotted on axes 1 and 2 respectively, with the distances between P, A, and C proportional to their growth rates, $\mu_i(s)$ observed in experiments. Precautionary note: it is tempting to call C and P ‘bacterial lion’ and ‘jackal’ respectively as permanent labels to be used for the interpretation of numerous descriptive ecological data in the past or expected from future observations. But it would not be perfectly correct because the ordination procedure does make sense only within the analyzed subset of chosen isolates. In other circumstances, P could display itself as a ‘lion’ in the fight with other than A and C competitors. We should also realize the multidimensional nature of the real ecological space with a multitude of factors affecting the outcome of a real-life competition. Having said that, we anyway continue the description of general trends and attempt to summarize the specific biokinetic features of microorganisms associated with their predominant life strategy.

Table 5 Typical growth patterns of soil bacteria associated with their life strategies.

Cultivation conditions	Products of r-selection (<i>Pseudomonas</i> , <i>enterobacteria</i>)	Products of L-selection (<i>Bacillus</i> , <i>Clostridium</i>)	Products of K-selection (<i>Arthrobacter</i> , <i>Caulobacter</i>)
Batch culture from lag-phase to starvation decline			
Dialysis culture: cell mass dynamics			
Chemostat transients: dynamics of cell mass after increase of dilution rate, D ($\downarrow$)			
C-limited chemostat culture: steady-state biomass versus D . Arrow indicates direction of D changes

Fig. 6 The concept of life strategies is graphically illustrated using animalistic symbols. Five familiar microorganisms are placed within a triangle space as a crossing point (shown for *Pseudomonas*) of three ordination positions. The position is determined either in real or computer-simulated competition experiments with mixed cultures of microorganisms competing for limited resources under specified environmental conditions, see the text. Based on Panikov NS (1995) *Microbial Growth Kinetics*. Springer Netherlands.

r-Selected organisms

Table 5 summarizes the results of kinetic studies of microorganisms with contrasting degrees of impact of either r, K, or L-selection. In the most general terms, all prokaryotes and single-cell eukaryotes are much more impacted by the r-selection as compared with higher forms of multicellular life. They are simpler organized, reproduce with higher rates, and recover after any perturbation with the speed unthinkable for multicellular Animalia and Plantae. Anyway, some microorganisms carry more features beneficial for the opportunistic lifestyle. Examples are those microorganisms, which have been isolated already in the 19th century and are most thoroughly studied today: enterobacteria including the model #1 *E. coli*, *pseudomonas*, baker, and fodder yeasts, 'saccharolytic fungi,' etc. Their dynamic behavior is erroneously considered to be typical for *all* microbes: rapid and balanced growth, short lag periods, and smooth transients. They dominate in those natural habitats that are frequently 'rejuvenated' to the pioneer succession stage: hot spots of substrate amendment, animal gut and feces, rhizosphere with diurnal fluctuations in exudation rate, and perpetual changes in 'address' of exudation loci due to apical extension of root hair. Exponential batch culture and plating are good simulations of such hot spots; that is why r-selected species appear first on isolation plates or in enrichment culture when we undertake a traditional survey of soils by plating and serial dilutions.

K-Selected organisms

K-selected bacterial species are much less amenable to isolation and cultivation. Probably most of the unculturable microbial species belong to this type of life strategy. The bacterial 'lions' are diverse microorganisms, many of them are called *oligotrophic* because they are found in great numbers in poor habitats, such as oligotrophic lakes or soil dispersion zone. The word *poor* stands for low levels of essential nutrients caused by either (i) aggressive consumption by microbiota or (ii) small supplies from external sources. The first option implies highly competitive pressure for use of nutrient resources rather than poorness (respective ecosystems can be quite productive and flourishing vs. deserts belonging to the 2nd option). The microbial community attains a mature successional stage when all available niches have been already occupied by the winners, i.e., those populations that successfully outcompeted others in a struggle for shared deficient nutrients. Thus, 'bacterial lions' instead of strong muscle, stamina, and deadly jaws, have extremely powerful high-affinity transporters that allow efficient nutrient uptake even from extremely diluted solutions, 10^{-7} – 10^{-10} M. In addition, they are characterized by low maintenance requirements and deliberately unbalanced growth (false diauxia, see below) without strong coupling between uptake and biosynthesis. That is a very valuable quality to keep the leading positions in the oligotrophic overcrowded community. On the other hand, when growing in the laboratory under traditional cultivation conditions, they look rather sluggish, fastidious, and unpredictable. We can picture such behavior as an artefactual response of an otherwise strong competitor to a wrong domestication protocol, a kind of *lion in captivity*. The best option for their cultivation is any continuous culture with cell retention: fed-batch, dialysis culture, or batch bioreactor with the C-supply via gas phase (volatile C-substrates, such as ethanol or VFA). Under these cultivation conditions, we avoid substrate and product

inhibition, and most oligotrophic microorganisms display a high yield and almost 100% viability even at extremely slow cell division (generation time up to months). In other cultivation protocols aimed at intensification of bioprocess, the growth patterns are characterized by: (1) the biphasic growth on the single C-source in a batch culture called the *false diauxia* (the first phase is just a filling of the C-storage compartment), (2) long survival under starvation, (3) oscillations and bistability (two or more steady-states at one dilution rate) in a chemostat at high D, indicating dynamic instability. To mathematically simulate the described abnormal behavior of *Arthrobacter* and other oligotrophic species, the SCM was elaborated to include the ROS type of intermediates with autoinhibition functions and the shortcut pathway of the C-storage (Table 5, the right column).

L-Selected organisms

Many L-selected microorganisms (bacilli, actinomycetes, some fungi) share the following common features: transition to dormancy as endospore under stressful conditions, use of antibiotics to suppress competitors, and a wider range of utilizable nutrients including recalcitrant polymeric compounds (pectin, starch, cellulose, lignocellulose), all of which require an extracellular breakdown by secreted hydrolytic enzymes. All the listed adaptations are combined to compensate for the competitive weakness of the L-selected organisms, their tendency to 'retreat from the battlefield' by switching to lower quality resources and repelling the enemies with poisons. If it does not help, then the last resort is to fully stop the metabolic activity and form endospores. Sometimes such qualities as the use of recalcitrant molecules and antibiotics are erroneously interpreted as a strength rather than a weakness of microorganisms, while sporulation is interpreted as a perfect survival mechanism. We have a convincing counter-argument based on the long-term experiments in dialysis culture (Table 5, the middle column): bacilli and clostridia were shown to be unable to sustain the near-zero growth and when the residual limiting substrate (glucose) concentration drops down to $\sim 10^{-7}$ M their cells entered a non-proliferating state without formation of the normal stress-resistant endospores. Note that the feast-to-famine transition observed in the regular batch culture is fully compatible with the sporulation process. In this case, the explosive growth of bacilli is stopped after depletion of the limiting nutrients (C- or N-source), and the following starvation serves as a trigger to start the multistep sporulation process producing eventually normal stress-resistant endospores able to germinate under adequate growth conditions. However, the deep substrate limitation in dialysis culture is a kind of 'trap' for bacilli and clostridia; they are provoked to start sporulation but are prevented from its completion by a slow non-zero feeding flux of nutrients through the dialysis membrane. The halfway dormancy is a pathological non-replicative state of cells with a low chance of recovery on the full-strength medium. As we discussed above, dialysis culture mimics an oligotrophic soil environment like a dispersion zone. The described phenomenon explains why sporulating bacteria never dominate the oligotrophic microbial communities.

Molecular basics of biokinetic diversity associated with life strategies

Are there any unique genes or specialized molecular mechanisms associated with different variants (r-K-L) of natural selection? Over the last two decades, several research laboratories tried to answer this question (see references under 'Further reading').

We start from the sporulating bacteria, impacted by the L-selection. It seems to be a straightforward task for the modern bioinformatic to distinguish them from the rest of the asporogenic prokaryotes. Classic microbiology textbooks usually refer to the *Bacillus* and *Clostridium* genera as typical spore-forming representatives of the microbial world. Now the list is approaching 100 genera, many of them found in soils. In the best-studied model organism *B. subtilis*, the process of sporulation involves over 500 genes. This list has been generated based on (i) proteomic profiling of endospores, (ii) RNA-seq profiling of gene expression during sporulation, and (iii) genome sequencing of asporogenic mutants. Many genes from the list are not uniquely attributed to the process because sporulation is tightly linked with cell division. Screening of other than *B. subtilis* aerobic spore-formers produced a shorter list of 60 orthologous genes essential for sporulation. Among them are Spo0A (the sporulation master regulator), sspA (acid-soluble spore protein A), dpaA, and dpaB (dipicolinate synthase subunit A and B). Further, it was concluded that firmicutes with genomes smaller than 2300 kb (equivalent to about 2100 protein-coding genes) are not able to produce endospores, therefore genome size can be used as an additional search filter. However, the most extensive recent survey of up to 400 completely sequenced firmicute revealed serious complications (Galperin et al., 2012): some firmicutes lack several essential sporulation genes, while other key sporulation genes including Spo0A were found in microorganisms that do not form endospores, e.g., cyanobacteria, proteobacteria, and spirochaetes. In summary, the bioinformatic approach so far failed to provide an easy way to estimate the abundance of the sporulating bacteria from the metagenomic soil surveys. Specific molecular mechanisms responsible for bacteriostasis of bacilli and clostridia in dialysis culture also remain unclear and are awaiting further investigations.

More genomic data are now available to draw the line between oligotrophic and copiotrophic microorganisms that evolve respectively under impacts of the K- and r-selection. First, a tight correlation was found between bacterial growth rate and the copy number of the rRNA gene involved in the ribosomal synthesis of proteins. Typical r-selected copiotrophic species (*E. coli*, *Vibrio*, *P. putida*, *Burkholderia cepacia*) contain 6–9 copies, while the oligotrophic *Caulobacter*, *M. smegmatis*, and *Sphingomonas* sp. contain 1–2 copies. The largest copy number was found in *Bacillus* and *Clostridium* (10–13 copies) which agrees with a common opinion that these bacteria have evolved as products of a mixed r/L-selection (Klappenbach et al., 2000).

Oligotrophic and copiotrophic microorganisms have a clear distinction in their permeases and other proteins with transporting functions. The balanced growth of copiotrophic microorganisms is at least partly explained by a tight coupling between transport and the following intracellular primary metabolic pathways (the PTS mechanism of glucose uptake). The more efficient growth of oligotrophic bacteria (higher yield, lower maintenance) is explained by the fact that they minimize the number of energy-intensive

ATP-binding cassette (ABC) transporters each having broad substrate specificity and high affinity to the wide range of nutrients (Lauro et al., 2009). The copiotrophs tend to express specialized transporters that involve greater energetic costs but provide more flexibility in transient kinetics minimizing the lag phase.

Life strategies and the problem of growth recalcitrance

Dependent on the method of calculation, from 70 to 99% of soil prokaryotes do not grow in the laboratory media (Stewart, 2012), the phenomenon is called *uncultivability* or *growth recalcitrance*. Several useful tactics have been developed, such as diluted media with soil extracts, antioxidants, growth factors, dilution to extinction, and many more (Stewart, 2012). Yet, the problem is not resolved. A common opinion is that recalcitrant cells grow in situ but microbiologists fail to reproduce their growth requirements in the laboratory. An alternative explanation is that recalcitrant cells belong to the category of VBNC (Viable but nonculturable) cells, a kind of dormancy state of low metabolic activity and zero growth rate caused by adverse environmental conditions. We described (Panikov et al., 2015) the irreversible formation of VBNC as ribosome-deficient cells accumulating in the continuous recycle culture of *P. putida* (Panikov, 2023, Part 1) and *B. subtilis* (Table 5, middle column). However, a more plausible explanation is that most not-yet-culturable microorganisms are the products of the K-selection (Watve et al., 2000). Indeed, the conventional isolation techniques are based on cell cloning, a process deriving a population of cells from a single cell exposed to excess nutrients. In other words, the isolation protocol is an ideal reproduction of the r-selection, or a mixed r/L selection if a single cell is allowed to divide at extreme pH, temperature, osmolarity, etc. A completely different isolation protocol should be implemented for the K-selected species, which evolved to grow in the overcrowded environment at low nutrient concentrations established in the climax communities. These bacteria grow slowly in situ but during the standard isolation, their growth is stopped by a high concentration of catabolic substrates (actual inhibitors are likely to be ROS as by-products). Instead of conventional cell cloning (subcritical dilution and exposure to nutrient excess), the K-strategists must be isolated by using a continuous enriched culture with heavy inoculum and long incubation time sufficient for self-maturation.

Now we move to the last section of this overview to see how the biokinetic diversity linked to life strategy can help to understand decomposition in soil.

Decomposition kinetics

Decomposition is one of the most essential soil processes potentially affecting the Earth's atmosphere, a key point of the Global Change agenda. Not surprisingly, decomposition is presently the subject of diverse interdisciplinary studies involving mathematical simulations aimed at a better mechanistic understanding of the process and the prediction of its dynamics. Below we outline several alternative ways of presenting the biokinetics of substrate decomposition in soil.

Decomposition as self-decay

The simplest assumption is that the rate of decomposition is proportional to the instant content of DOC (s) coming to the soil as plant litter. Such assumption implies the first-order decomposition kinetics introduced to soil science about 80 years ago (Jenny, 1941):

$$\frac{ds}{dt} = -ks \quad (37)$$

The rate constant k is allowed to vary as dependent on climatic conditions (temperature, soil moisture) and soil properties (texture, trophic status, biological activity). The next logical step was to account for the notoriously known heterogeneity of organic matter subjected to decomposition, it was done by presenting the variable s in Eq. (37) as a sum of n components, each one having its own self-decay rate constant:

$$\frac{ds}{dt} = -k_1s_1 - k_2s_2 - \dots - k_ns_n = -\sum_{i=1}^n k_is_i \quad (38)$$

Typically, n varies from 3 to 10 to keep mathematical simulation reasonably compact although some authors suggest a non-reductionistic approach of accounting for the whole array of DOC detectable by modern analytical techniques such as solid-state ^{13}C NMR spectrometry (Mazzoleni et al., 2012). Fig. 7 shows as an example the popular CENTURY ecosystem model (Parton et al., 2001), which stratifies organic carbon into nine pools associated with three subgroups: (i) the aboveground plant litter, (ii) root litter, and (iii) soil organic matter (SOM). Inside each subgroup, there are labile and resistant C-pools as dependent on the lignin-to-N content. According to Eq. (38), the chemical structure of the selected C-pools plays the leading role in the decomposition kinetics rather than the soil organisms, which perform the process. Most probably it stems from the last-century paradigm established for the rare model microorganisms (*E. coli*, *S. cerevisiae*) that respond specifically to single individual C-sources, some compounds are utilized instantly, some slowly, and some left intact. In a similar way, the ecosystem modelers assumed that every soil compound has its own unique degradability potential, and an adequate simulation model should solve two major tasks: (i) to combine compounds with a similar degree of degradability into a few pools or clusters (too many pools make model cumbersome),

Fig. 7 Soil decomposition simulated by the CENTURY model. The boxes stand for various C-pools that belong to the aboveground plant litter (light green), root litter (light gray), and soil organic matter (light orange). There are two microbial pools, the first one is localized within a surface plant litter (green frame), and the second one spreads between the mineral soil layers. The chart based on Parton B, Ojima D, Del Grosso S, and Keough C (2001) *CENTURY Tutorial. Supplement to CENTURY User's Manual*. NREC Pub. Natural Resource Ecology Laboratory, Colorado State University.

and (ii) to account for the modifying effect of environmental factors, e.g., fluctuating temperature, moisture, as well as specific soil qualities potentially affecting process kinetics, e.g., the clay minerals that bind organic molecules and slow down their degradation.

This paradigm has been gently criticized. For example, Davidson and Janssens (2006) stated that one and the same organic compound can display dramatically different rates of decomposition depending on the soil micro-environment, e.g., some molecules may become physically protected in the interior of soil aggregates. Another more serious deficiency is that Eq. (38) misinterprets the basic mechanisms of soil decomposition ignoring its essential systems qualities:

1. It assumes that SOM degradation proceeds *spontaneously* while in real life the process is driven by soil organisms (microbes and invertebrates), therefore decomposition dynamics must be simulated by equations containing the terms characterizing the community of the degraders, their abundance, and biokinetic parameters that establish feedback to the changeable soil environment.
2. Eq. (38) assumes that decomposable substrate is a mixture of compounds each of which is degraded *independently* and *simultaneously* as if plant litter has been split by magical chromatographic procedure into hundreds of purified individual compounds, each placed into a separate microtube and offered to soil degraders. However, real dead plant material remains consolidated and decomposition proceeds *sequentially* starting from the most accessible part (glucose, glycolytic and TCA intermediates, and other mobile compounds) that usually acts as catabolic repressors preventing depolymerization of even slightly more resistant plants polymers (starch, hemicellulose, cellulose). Lignocellulose is decomposed as a whole; the carbohydrate part is aerobically consumed with the formation of ROS (reactive oxygen species) that prime the oxidative degradation of the lignin. Thus, different C-pools *strongly interact* with each other, and these interactions have a striking effect on the process kinetics.
3. According to Eq. (38), decomposition in soil is a set of one-way degradation reactions converting SOM into waste products (CO_2 and H_2O), however, the real soil process combines the catabolic decay reactions with the biosynthesis of new compounds, such as degrader cells, their extracellular metabolites including macromolecules. Thus, the simulation of decomposition dynamics should include equations of microbial growth under very specific soil conditions of near-zero microbial growth encouraging secondary metabolism, formation of stress-resistant pigments (some resemble humic compounds), biofilms cementing soil particles into stable aggregates, and other multicellular structures essential for a better understanding of mature soil as a habitat and part of nature.

The biosynthetic reactions discussed above are usually referred to as the *transformation* reactions associated with decomposition. Recently, several attempts were made to improve Eq. (38) by making it mathematically more comprehensive and accounting for the combined effect of decay with transformations. It presents the SOM as a *continuum* of degradability using PDE, a differential equation in the partial derivatives (Carpenter, 1981):

$$\frac{\partial f(z, t)}{\partial t} + \frac{\partial V(z, t)}{\partial z} = -U(z, t)f(z, t) \quad (39)$$

Here $f(z, t)$ is the distribution of detritus components with respect to their susceptibility to microbial degradation, z , where z ranges between 0 and the maximum value z_m ; $V(z, t)$ is the amount of detritus converted into more or less available compounds; and $U(z, t)$ is the degradation rate. However, this elegant equation has never been filled with specific biological information and applied to soil decomposition studies. Two subsections below dealing with the decomposition of simple individual compounds and cellulose give an alternative to the self-decay paradigm placing the emphasis on soil organisms responsible for decomposition, and their specific biokinetic features imprinted in their life strategies.

The mean residence times and half-life: the interpretive nuances

Decomposition kinetics is often characterized using half-life ($T_{0.5}$) and the mean residence time, MRT (τ). The half-life is the time required for a given individual compound or C-pool to be decomposed by 50%. The relationship between $T_{0.5}$ and k is found after integration of Eq. (37) at initial conditions, $s = s_0$ at $t = 0$, and $s = 0.5 s_0$ at $t = T_{0.5}$:

$$s = s_0 e^{-kt}, \quad \text{if } t = T_{0.5}, \quad \text{then } 0.5s_0 = s_0 e^{-kT_{0.5}} \quad \text{and} \quad T_{0.5} = \frac{\ln 2}{k} \quad (40)$$

As applied to Eq. (38), the half-life is calculated for each C-pool as $T_{0.5i} = \ln 2/k_i$.

The *mean residence time*, MRT is the average length of time that an entity, in this case, a decomposable i th soil compound will remain in a studied system. The best relevant MRT illustration comes from soil zoology (Fig. 8): the earthworms swallow pieces of plant litter, and the moving food lump undergoes digestion, being eventually released as excrement. Here the MRT is the time taken for a single litter bite to move from the mouth to the anus; MRT can be estimated by feeding the worms with the stained plant material. The rate of decomposition is calculated as (note similarity with Eq. 4):

$$\frac{ds_i}{dt} = \frac{s_i^{\text{in}} - s_i^{\text{out}}}{\tau_i} \quad (41)$$

The soil decomposition does not allow such a straightforward interpretation of MRT, rather it is closer to the variant of MRT called *turnover time* (τ). It is defined as the ratio of the pool size to the flux in or out of the pool; then as applied to Eq. (38), $\tau_i = s_i/k_i$; $\tau_i = 1/k_i$. The expressions for τ_i and $T_{0.5}$ look very similar; they differ just by the constant quotient $\ln 2 \approx 0.693$ although their original premises are completely different. Let us see where the problem lies by looking at the process kinetics obeying Eq. (38). We need to update this equation, first, by adding the source of DOC, F_i and, second, by assuming the steady-state status of the soil system achieved when the input exactly matches the output:

$$\frac{ds_i}{dt} = F_i - k_i s_i = 0 \quad \therefore \quad \bar{s}_i = \frac{F_i}{k_i} = F_i \times \frac{1}{k_i} = F_i \times \tau_i \quad (42)$$

Here $\bar{s}_i$ is the steady-state pool size, which is the product of two terms, the input F_i multiplied by τ_i . It clarifies the meaning of the parameter τ distinct from the half-life $T_{0.5}$: the MRT stands for the time required to rebuild the soil pool from a continuously running source, F , while $T_{0.5}$ is associated only with decay, the negative component of the C-balance. A simple numeric example: let us assume that the content of free amino acids (AA) extracted from field soil varies over the summer season around 10 ppm (mg/kg soil), let it be a steady-state or a near steady-state pool $\bar{s}$. In an independent manipulation experiment, added to the same soil AA was degraded with an average rate of $k = 0.5 \text{ d}^{-1}$. From Eq. (33) we can easily estimate the source strength, $F = 10 \times 0.5 = 5 \text{ ppm/d}$, which otherwise is a very challenging task. The MRT, $\tau = 1/0.5 = 2 \text{ d}$ implies a very high turnover rate, once per 2 days, but does not say anything about the decomposition. In a thinking experiment, if we stop the input ($F=0$), then after $\tau = 2$ days the pool will be depleted down to $\sim 37\%$ and will proceed with the same pace; the 50% declines every $T_{0.5} = 1.39$ days. Thus, we see that τ and $T_{0.5}$ values are not identical although close to each other.

Fig. 8 Digestive tract of earthworm.

In conclusion, the MRT does make sense when applied to the open soil systems having both positive (PP, rhizodeposition, etc.) and negative (decomposition, leaching, crop harvesting) parts of the C balance. In this case, MRT or turnover parameters allow estimation of the true decomposition hidden by soil pool restoration from some non-accounted sources. On the other hand, for soil decomposition under conditions excluding refill (e.g., the litter bags technique), the $T_{0.5}$ is a better option.

Decomposition of simple individual compounds

The realistic kinetic models represent the decomposition process as a result of the growth and activity of decomposer organisms. DOC entering soil are their C-source. Therefore, the changes in biomass must be accounted for in the kinetic expressions. Unfortunately, monitoring the status of the microbial community remains a very challenging procedure. Either classic (direct microscopy, plating, enrichments) or modern molecular techniques (metagenomic surveys, RNA seq, FISH - Fluorescence In Situ Hybridization, SIP - Stable Isotope Probe, etc.) are tedious or expensive and provide mostly single-point data rather than the required dynamic picture with high temporal resolution. The good news is that microbial growth can be *inferred* from the dynamic record of decomposition. In the case of laboratory incubations of soil, test organic compounds are added and the decomposition time course is followed by respirometry (CO_2 evolution rate) or by analyses of the residual organic material. The first technique is especially convenient because it is non-destructive and can be performed automatically in a series of multiplexed soil samples. The principle of reconstruction is as follows. Experimental data on substrate (s) uptake and CO_2 produced (p) are fitted to the SCM or any other advanced growth models able to simulate a self-regulatory behavior of microorganisms. The model describes sources and sinks for three variables, e.g., s , p , and x (cell biomass) using the non-linear regression as a curve-fitting procedure minimizing the simulation error. The missing experimental data on cell mass are constrained by the top and bottom limits and found as a part of inverse problems solution together with the coefficients of the model. Note that this approach is meaningful only in the case of precise lab experiments with soil amended with readily available organic compounds that demonstrate high rates of degradation. These compounds must be added to soil at an amount sufficient to double (at least) the background respiration level.

As shown in Table 6, we can confidently identify those rare cases when the decomposition dynamics are not associated with microbial growth, when degradation starts instantly and then progressively declines over time. It could be a spontaneous abiotic self-oxidation of unstable organic compounds that is expected to follow the first-order kinetics (Table 6, row 1), or the degradation process catalyzed by either the extracellular or soil enzymes, or by the non-growing but catabolically active cells (growth arrest is discussed below) that follows the enzymatic Michaelis-Menten kinetics (Table 6, row 2). Microbial growth associated with decomposition is manifested as an exponential increase in the degradation rate (Table 6, rows 3 and 4). The short-term soil incubation experiments limited by the exponential phase of the growth (row 3) do not give a full picture of the decomposition cycle but can be used in practice as a quick indirect method to estimate the biomass of certain physiological groups of soil microorganisms utilizing given organic compounds (Panikov and Sizova, 1996). It is equivalent to the classic SIR (Substrate Induced Respiration) with one essential step forward: the conversion factor from SIR to biomass is found individually for each sample as parameter x_0 of the verified mechanistic SCM model (Panikov, 1995). Besides, there is a bonus of qualitative characterization of the microbial community (parameter r_0), which is a reporter for the macromolecular composition of cells in situ.

As expected, the soil is much more complex than a trivial batch culture. Soil bacteria are still mostly unknown, and some recently discovered species can deviate significantly from the canonic exponential pattern. Notably, the dominating K-selected oligotrophic bacteria can display a *false diauxia* (Table 5, first row). In soil samples taken from the dispersion zone, glucose decomposition shows a characteristic wavy dynamic pattern (Table 6, row 5) with two peaks of glucose uptake, one taking place at the start of incubation and the second in the middle of the process. A remarkably similar pattern was found in a batch culture of *Arthrobacter globiformis* and other K-selected oligotrophic species. The first phase is attributed to filling the storage compartment, while the second one is due to normal exponential growth. This pattern can be one of the major reasons for the *priming effect* phenomenon, usually interpreted as the co-metabolism of recalcitrant indigenous SOM by an added labile compound. Our interpretation states that labile amendment 'wakes up' the half-dormant microbial residents that remain activated for a long time period after depletion of the primer.

Decomposition of pure cellulose

Significantly more challenging is the decomposition kinetics of the dead structural polymeric plant material, containing lignocellulose, pectin, tannin, waxes, and other recalcitrant OM. Contrary to monomeric substrates, plant polymers are degraded by extracellular enzymes, and the depolymerization products are shared by the rest of the community (the *cheaters* in the modern molecular vocabulary). In addition, structural plant tissues are poor in the biogenic elements (N, P, Mg, Fe...), while the production of extracellular enzymes require extra amounts of these elements for ribosomal protein synthesis. The deficiency of biogenic elements coupled with C-sufficiency provides a high risk of metabolic imbalance and arrest of microbial activity. The non-intentional metabolic arrest called *bacteriostasis* and *fungistasis* is still a mystery in microbial physiology; it can occur without the deliberate application of toxic materials. One example is the 'substrate-accelerated death', severe catabolic repression of cells exposed to a high concentration of catabolite (e.g., glucose) after non-growing conditions, especially caused by deficiency of anabolic substrates (N, P, K...). The natural manifestations of microbial metabolic arrest include accumulated dead organic matter in soils of various degrees, from shallow plant litter layers on the forest floor to multimeter peat deposits in ombrotrophic and

Table 6 Decomposition kinetics of simple individual compounds added to soil, based on (Panikov, 1995).

Condition, model	Residual substrate	CO ₂ production rate	Microbial biomass
1. Negligible effect of microbial growth, the process rate does not depend on microbial biomass. Eq. (37), the first-order kinetics typical for abiotic reactions			
2. Negligible effect of microbial growth, the process does not depend on microbial biomass. The Michaelis-Menten kinetics typical for enzymatic reactions			
3. Degradation process is accompanied by unlimited microbial growth. A simple exponential growth, or Eq. (33) under simplified conditions, $s \gg K_r$			

4. Degradation process is accompanied by substrate-limited microbial growth.
The Monod model, or Eq. (33), the full SCM.

5. Degradation process is accompanied by the growth of K-selected microorganisms.

Time, h

mesotrophic bogs. A sustainable microbial decomposition under described challenging conditions is made possible only by the cooperative efforts of the entire community.

For the sake of clarity, we illustrate the process complexity using pure ash-free cellulose incubated in forest soil under controlled environmental conditions (Fig. 9). The minimal structure of the decomposer community turned out to contain three microbial groups:

- 1) L-selected hydrolytic populations that produce extracellular cellulases. As we argued in the previous section, switching to low-grade nutrients is a sign of L-selection typically combined with two other qualities, the production of antibiotics and easy transition to metabolic arrest. Since all L-selected species fluctuate around the point of extinction, then the production de novo of extracellular depolymerization enzymes is a vulnerable decomposition step that can be very sensitive to the availability of these organisms and their physiological state.
- 2) r-selected copiotrophic organisms under adequate energy supply capable of explosive growth and mitigating the deficiency of mineral nutrients. Specifically, they can fix atmospheric N_2 under a shortage of N, and mobilize K and P by dissolving insoluble salts through the secretion of chelating exometabolites.
- 3) K-selected oligotrophic populations capable of scavenging monomeric products diffusing from decomposition hot spots. Their remote location makes them less dependent on the deficiency of biogenic elements.
- 4) In addition to the live microbial cellulose degraders, there are free cellulases immobilized on soil particles providing some background level of depolymerization activity.

The chain of events after cellulose is added to soil is as follows: (i) added polymeric substrate induces microbial synthesis of extracellular cellulases releasing mono- and oligosaccharides from polymeric substrate within the decomposition hot-spots; (ii) sugar uptake induces a short-term (ephemeral) microbial growth of the group 1 until one of the nutrients, for example, N

Fig. 9 Cellulose decomposition dynamics. Cellulose (as ash-free filter paper) was added either to the freshly collected forest soil (**left** column) or the same soil after drying and rewetting for activation of the cellulolytic microorganisms (**right** column). The incubation took place at constant moisture and 25 °C with recording cellulose weight loss (**top** panel) and CO₂ evolution rate (**bottom** panel). Microbial community dynamics (**middle** panel) and other curves were simulated by the SCM-based model (Panikov, 1995) assuming the involvement of extracellular hydrolytic enzymes and three indicated microbial groups, see explanations in the text.

becomes depleted; (iii) N-starvation prevents further production of new hydrolytic enzymes, growth of the L-selected organisms is stopped and they enter a dormant stage; (iv) cellulose is still degraded by the accumulated extracellular enzymes, the released oligo- and monosaccharides are accumulated dramatically, increasing the C:N ratio and provoking explosive copiotrophic growth combined with N_2 fixation; (v) microbial group 2 depletes accumulated C-monomers, starvation causes their lysis accompanied by release of NH_4^+ , the N-deficiency progressively evolves into the double N:C and then a pure C-limitation; (vi) group 3 of the K-selected oligotrophs continues to function as a sink for depolymerization products, preventing product inhibition and eventually resulted in the complete degradation of cellulose. Verbal description is translated into a mathematical model which gives fair agreement with observation (Fig. 9).

The inadequacy of the self-decay model (Eq. 38) is evident from the described experiments. In the same soil and under identical hydrothermal conditions, cellulose is decomposed at a dramatically different rate, depending on the state of the decomposer community. Two perturbation factors, soil NPK fertilization, and drying-rewetting 'wake up' the L-selected hydrolytic microorganisms and accelerated the decomposition. The most pronounced effect was achieved by using one dry-rewet cycle before the incubation (compare the left and right parts of Fig. 9). This perturbation is a stressful procedure causing partial damage to microbial cells accompanied by the leakage of cell constituents into the soil solution. Probably, some inhibitory or repressing metabolites responsible for metabolic arrest are also released from their cells during the rehydration cycle giving a chance for the hydrolytic populations to proliferate. It is interesting that healthy native soils have, by default, a repressed state of microorganisms with high hydrolytic activity, although soil still has a background depolymerization activity level due to the presence of soil enzymes (slow zero-order decomposition, Fig. 9, left column). Thus, a restricted soil decomposition looks like a normal physiological state contrary to the pathological state of the NPK-overdosed arable soils where high hydrolytic activity is combined with toxicity caused by the L-selected species, mostly fungi.

Decomposition of plant litter

The last step from cellulose to lignocellulose and the whole plant litter brings the following complications: (a) in lignocellulose the polysaccharide component is made less accessible to microbial enzymes by a combined effect of low ash content, tough texture, and toxicity of the lignin, (b) the higher heterogeneity of plant litter due to the presence of other than cellulose polysaccharides, as well as waxes, and aromatic compounds often considered as inhibitors and (c) a more complex soil community. However, the degradation of cellulose and lignin is carried out jointly; the carbohydrate component is used as an available C-source generating during catabolic reactions the peroxides and other ROS instrumental in the spontaneous oxidative destruction of lignin. Although lignin slows the decay rate, lignocellulose is decomposed as a whole, and pure lignin is not accumulated at late decomposition stages although the lignin-to-N ratio often increases. Therefore, the kinetic mechanisms of decomposition revealed for cellulose alone are also applicable to lignocellulose.

Conclusion and prospects for future developments

How to handle soil complexity?

Complexity increases with organizational levels, and so do process kinetics. In *chemistry*, reaction rates obey the *law of mass action* translated into simple zero-, first-, or second-order kinetics. The *enzymatic* reactions proceed through the dynamic enzyme-substrate complexes, and their rates follow a mixed-order Michaelis-Menten kinetic that opens a multitude of subtle regulations, e.g., reversible inhibition and activation, allosteric effects, cooperativity, etc. At the *cellular level*, the differential gene expression adds a dramatic increase in complexity since the variable environmental conditions (temperature, substrate concentrations, toxicity, etc.) affect the growth rates directly and through the self-adjustable changes of the macromolecular composition of cells. Finally, the *soil community* produces further complexities: (i) multiple species of the same metabolic type interacting through competition or metabiosis, (ii) other species including microbial predators and parasites, (iii) a multifaceted mosaic environment subjected to occasional perturbations and stresses. The conventional microbial kinetics focuses on the first three organizational levels (chemical, enzyme, and microbial growth kinetics). Here we demonstrate several new approaches that allow us to address the soil complexity. *First*, the soil biokinetic diversity was shown to be categorized into a few types (we suggested six), each one corresponding to the unique laboratory cultivation. It reduces soil complexity and allows experimental verification of each kinetic module based on reliable laboratory data. *Second*, the nutrient supply (flux, pattern, spectrum) has been selected as the *primary environmental factor*, and it is obligatory to include the respective variable, the concentration of limiting nutrient. Other factors are optional, and it helps to keep the model compact and manageable. *Third*, introducing the concept of life strategies allowed a justified aggregation of the multitude of potential soil competitors into a limited number of behavioral groups (e.g., L-selected hydrolytic, r-selected copiotrophic, and K-selected oligotrophic microbial clusters in the model of cellulose decomposition). According to Occam's razor principle of parsimony, the number of groups is not formally limited but should be kept at a pragmatic minimum sufficient to explain the observed dynamic pattern or its self-regulation. *Fourth*, similar aggregation is made for microbivore soil organisms (or parasites) accounting for the biological elimination. It is included in most cases; the only exceptions are the dispersion zone (too sparse prey density provides immunity) and the short-term soil incubations (within a predator's lag phase). *Fifth*, biokinetic studies benefit from combining field observations with laboratory experiments. Specifically, soil

incubations with added substrates and soil-plant microcosms reduce complexity by excluding stochastic events and allow a thorough recording of transient regimes, e.g., perturbations, and ecological successions with required precision and accuracy.

Still, what is the rate of microbial growth in the soil?

Eight different approaches for estimating microbial growth rates in nature have been reviewed. Some were included just for the sake of historical accuracy. The most practical for soil studies are the non-destructive methods using gaseous substrates and products, e.g., heterotrophic $^{14}\text{CO}_2$ fixation under isotope incorporation techniques and CO_2 formation under soil respiration. However, it would be wrong to have the SGR assessment as the only research goal. The first four approaches discussed dealt with simple communities in a defined environment. But most of the soil-based ecosystems display remarkably wide SGR variation over time and across the community. Therefore, a single average SGR is a worthless characteristic apart from compact microbial communities at near steady state and having a narrow SGR distribution. Examples are long-term fallow soil (vegetation-free plots dominated by K-selected slow-growers) and the invertebrate gut microbiome (dominated by r-selected fast-growers). Otherwise, a more reasonable goal would be to identify all essential sources and sinks for microbial growth, record the process, and fit the data to the growth model, the SGR dynamics will be found as a part of the model's outputs. We used this way when discussed soil fluctuations (Fig. 2) and found that growth rate cannot be constant, instead, the SGR fluctuates between the high and low limits, the upper limit is attained once per week, that day a rhizomicrobial population completes a full division cycle, the following 5–7 days bacteria grow slower making another 2 or 3 divisions. It is very fast growth; similar growth intensity can be detected in the gut of animals and in hotspots of decomposition. Soil microorganisms located in the dispersion zone grow much slower, displaying long generation times extended to few weeks or months. Soil fungi responsible for decomposition of plant litter grow with SGR between these two extremes.

What did we learn from kinetic studies?

The most beneficial feature of biokinetics is that it helps to organize empirical data (field observations, experimental results) into the non-contradictory concept and respective mathematical model. Any inadequate assumptions are discarded during the model's construction based on the mismatch between observation and simulation. This chapter gives several examples of incremental progress in the understanding of soil biodynamics: periodic soil fluctuations, the priming effect, ecological successions accompanying cellulose decomposition, the mechanisms of microbiostasis, and the uncultivability phenomenon. Application of the SCM model to short-term soil incubations with added substrates allowed the responder biomass estimation without any empirical conversion factors. In the attempt to correct the absurd simulation results (too low and negative average SGR, described under Seasonal decomposition of organic matter), we detected the published misinterpretations of the physiological state of soil biota (maintenance, cryptic growth) and revised a theoretical basis of the chase-pulse method designed for assessment of root exudation (RE), the most significant C-source for microbial decomposers in soil. We treated RE as an intermediate of the plant production process appended with a microbial loop (Eqs. 22–30). It is a standard modeling approach in biokinetics to describe the reactant A conversion to the product P via the intermediate I. The main obstacle in the past was that A (PPA and phloem translocation) is beyond the traditional scope of soil biology. The 'moral of the story' is that a full understanding of soil processes cannot be achieved without touching other parts of the ecosystem, we need to look inside the green aboveground parts of plants as well.

What we missed

Sure, it is impossible to embrace all the areas potentially accessible using the biokinetic approach. We missed the fungi and actinomycetes as mycelial forms of microbial life growing as a network of branched hyphae rather than unicellular bacteria. Another important missed point is the symbiosis of prokaryotes (Rhizobium and Frankia) and mycorrhiza with plants, which has tremendous theoretical significance and great biotechnological potential. Other missed points include (although not limited to) the phages, Bdellovibrio, and microarthropods as selective elimination factors of the growing microorganisms, plate count as a kinetic tool to characterize the microbial physiological state, the quantitative microbial morphology helping extraction of useful information from direct soil microscopy, beneficial spontaneous mutations as one of the mechanisms affecting microbial dynamics and other topics. On the practical side, biokinetic knowledge is especially important and helpful for the optimization of various bioengineering projects aimed at soil bioremediation from pollutants, and for the development of sustainable 'green' agriculture.

Abstract

Globally, the amount of soil organic carbon (SOC) is more than twice the carbon in the atmosphere or living vegetation. SOC is an important indicator of the condition of a soil because it influences almost all soil biological, chemical, and physical properties and processes. Loss of SOC, accelerated by soil erosion and disturbance, are affected by C management. This chapter explores the carbon cycle, soil-forming factors, composition and functions of soil carbon and the management practices affecting the levels of soil carbon.

Key points

- Soils contain several important C pools and play an essential role in the global C cycle.
- Development of conservation agriculture practices have increased SOC.

Introduction

Carbon is the fundamental building block of all life on Earth. It is present in the atmosphere, plant and animal life, nonliving organic matter, fossil fuels, rocks, and is dissolved in oceans. Carbon is the sixth-most abundant element in the universe, after hydrogen, helium, oxygen, neon, and nitrogen. Concerns about increasing carbon dioxide levels in the atmosphere have resulted in greater public and scientific interest in the global carbon cycle. Since the mid to late 1800s, fossil fuel use, expansion of cultivated agriculture, and forest clearing have led to an increase in atmospheric CO₂ from 260 ppm to current levels of approximately 410 ppm (Smith et al., 2014). Most of the recent increase in atmospheric CO₂ is attributed to the burning of fossil fuels. Current levels of CO₂ are higher now than in the past 1000 years. The increase in CO₂ is of concern because CO₂ is one of the three primary greenhouse gases, the other two being methane (CH₄) and nitrous oxide (N₂O) (Paustian et al., 2019). These three gases retain heat that normally radiates from the Earth's surface. The concern is that elevated levels of CO₂ could increase the heat retained in the atmosphere, thus leading to global warming. Observations have recorded a 0.6 °C increase in the global temperature since 1900 (NOAA, 2014, Smith et al., 2014).

The basic carbon cycle of life is: (1) the conversion of atmospheric carbon dioxide to carbohydrates by photosynthesis in plants; (2) the consumption and oxidation of these carbohydrates by animals and microorganisms to produce carbon dioxide and other products; and (3) the return of carbon dioxide to the atmosphere (Fig. 1). On a global level, the carbon cycle is more complex and involves carbon stored in fossil fuels, soils, oceans, and rocks.

Soils contain several important C pools and play an essential role in the global C cycle. We can organize all the carbon on Earth into five main pools, listed in order of the size of the pool:

1. Lithosphere (Earth's crust): This consists of fossil fuels and sedimentary rock deposits such as limestone, dolomite, and chalk. This is the largest carbon pool on Earth. The amount of carbon in the lithosphere is 66–100 million Pg (1 Pg = 10¹⁵ g). Of this amount, 4000 Pg consists of fossil fuels.
2. Oceans: Ocean waters contain dissolved carbon dioxide and calcium carbonate in marine organisms. The amount of carbon in oceans is 38,000–40,000 Pg.
3. Soil organic matter: The amount of carbon stored in soil organic matter is 2500 Pg (Lal, 2004);

Fig. 1 Simplified representation of the terrestrial carbon cycle between the atmosphere, plants, and soil.

4. Atmosphere: The atmosphere consists primarily of carbon dioxide, carbon monoxide, and methane. The amount of carbon in the atmosphere has increased from 578 Pg in 1700 to about 766 Pg in 1999, and continues to increase at the rate of about 6.1 Pg year⁻¹.
5. Biosphere: The biosphere consists of all living and dead organisms not yet converted into soil organic matter. The amount of carbon that resides in the biosphere is 540–610 Pg.

In the terrestrial system, soils play a key role both in reservoirs and fluxes in the plant–soil–atmosphere continuum. Carbon in soils is present both in inorganic and organic forms. Carbon comprises up to 10% of the soil mass, except for waterlogged soils such as Histosols that contain up to 30% carbon. The surface horizons of most soils contain less than 3% carbon. Most of the carbon that resides in the soil is in the organic form, except for arid soils and some soils formed from carbonate parent material. While carbon is a relatively minor component in terms of mass, it serves an important function in soil and the environment.

Fluxes

The largest fluxes of the carbon cycle are those that occur between the atmosphere and the vegetation and oceans. Carbon enters the soil primarily through plants (Fig. 1). During photosynthesis, plants convert CO_2 into organic carbon for growth. The estimated fixation by photosynthesis is approximately 62 Pg year⁻¹. This plant carbon enters the soil through root exudates, root turnover, and the addition of aboveground plant material. Upon their death, plant tissues decompose, primarily by soil microorganisms, with much of the carbon in plant material eventually being released back into the atmosphere as CO_2 . Respiration is estimated to release 62 Pg C year⁻¹, which balances photosynthesis. This compares with the 5 Pg year⁻¹ released by burning of fossil fuels; however, the release of C by burning of fossil fuels is not offset by a sink, thus resulting in the dramatic increase in atmospheric CO_2 . In some cases, under anaerobic conditions, methane (CH_4) is produced by microorganisms. However, soil microorganisms also consume CH_4 under aerobic conditions. Approximately 7% of the atmospheric C is recycled between plant uptake and microbial respiration. Thus, plant productivity and microbial respiration are the two key mediators between atmospheric CO_2 uptake and input.

Soil-forming factors

The level of organic carbon in soils is a function of climate, topography, biology (plant, fauna, and microorganisms), parent material, and time. These are the same factors that affect soil development. The first few years after a disturbance, such as soil tillage,

soil carbon increases relatively dramatically but slows until equilibrium is attained under the conditions of the existing environment. This is easily seen after reclamation of mined lands or conversion of cultivated cropland to permanent grasslands. A change in the environmental conditions with climate or management can alter the equilibrium levels. The equilibrium is reached as plant inputs balance the outputs of microbial respiration. The soil organic C levels are a result of biological recalcitrance and physical and chemical stabilization of the carbon, to be discussed later.

Climate is the most important factor governing soil organic carbon levels. Climate through water and temperature affects plant productivity and microbial activity. Hot climates, where water is restricted, have the lowest soil organic carbon levels because plant production is limited. Deserts are characterized by this environment. In the USA, precipitation increases from the Rocky Mountains eastward, thus resulting in greater soil carbon levels. This general increase in soil carbon is due to precipitation enhancing plant productivity.

Vegetation type can also influence the soil organic carbon levels through composition and production of the plant biomass. Plant materials vary in their decomposability due to chemical differences. Lignin and other polyphenolic substances decrease the decomposability of the plant material. Grasses tend to promote higher soil organic carbon than agricultural systems. Grasses have not only high productivity but also allocate more photosynthate belowground. The large densities and intense turnover of grass roots tend to favor formation of soil organic carbon. Although forests also sequester carbon, a greater proportion of that carbon is in woody biomass and litter (O horizon) (Sarto et al., 2020c). There are differences among crop species in the ability to sustain soil organic carbon levels. In general, high residue-producing annual crops such as corn, wheat, and grain sorghum replenish the supply of carbon to the soil. Low residue-producing crops, such as cotton and soybeans, tend to deplete soil organic carbon levels.

Parent material affects levels of soil carbon through the effect on texture, mineralogy, and pH. The amount and type of clay in soils also influences the ability of the soil to adsorb carbon compounds to clay surfaces and form stable soil aggregates, which contribute to the protection and stabilization of soil organic carbon.

Topography affects soil organic carbon levels through effects on microclimate, runoff and erosion, and evaporation. Lower slope positions often have higher organic carbon levels because of deposition and greater plant production. Slope positions with excess water also restrict microbial decomposition, resulting in the buildup of soil organic C.

Functions

Soil carbon is the most important addition to soils as it affects their properties. Carbon as soil organic matter alters the physical, chemical, and biological properties of the soils. Organic matter is a primary indicator of soil health defined as “the capacity of soil to function as a vital living system, within ecosystem and land-use boundaries, to sustain plant and animal productivity, maintain or enhance water and air quality, and promote plant and animal health” (Doran and Zeiss, 2000) (Fig. 2). Improvements in soil organic matter create a beneficial environment, leading to increases in plant growth. Increasing soil carbon stocks would increase agricultural resilience and fertility and reduce GHG emissions from soils (Paustian et al., 2019).

Fig. 2 Relationship between soil organic carbon, soil structure, and microbial activity.

Physically, soil organic matter improves aggregation of soil particles. Improved aggregation results in better soil structure, allowing for movement of air and water through the soil as well as better root growth. More stable soil structure results in less soil erosion, which retains nutrients on the land and protects water quality. Higher levels of soil organic carbon reduce bulk density, thus providing an improved rooting environment. In addition, organic matter holds water, an important attribute for plant growth in arid and mesic environments. Higher soil organic matter decreases soil crusting and increases water infiltration rates which enhance plant productivity and thus the return of plant material to the soil.

Chemically, soil organic carbon increases the cation exchange capacity of the soil. Soil organic matter can contribute 20 to 80% of the soil's cation exchange capacity. Cation exchange is important for the retention of many nutrients. Associated with the organic carbon are organic-bound nitrogen, phosphorus, and sulfur which, upon decomposition, provide slow release of these nutrients for plant production. In some cases, soil organic compounds enhance the chelation of metals, thus increasing the bioavailability of trace elements required for plant growth. Soil organic carbon often provides binding sites for many anthropogenic chemicals, thus minimizing leaching of hazardous chemicals through the soil profile or making them less available, which reduces toxicity.

Biologically, soil organic carbon is the source of carbon and energy for most soil microorganisms and fauna. Increased soil organic carbon enhances the biomass and diversity of the soil biota (McGowan et al., 2019; Sarto et al., 2020a). Since the soil microbiome drives energy and related biogeochemical transformations in soil, plant nutrient availability is often enhanced with the increase in soil microbial biomass and activity. Some organic compounds in the soil also exhibit plant growth-promoting properties, further enhancing plant productivity. Increasing crop frequency and species diversity in agricultural systems promote nutrient cycling, microbial biomass and activity, aggregate stability, and soil protection. Crop diversification increases the soil microbial biomass (Bonini Pires et al., 2020). The conversion of native biomes to agricultural systems shifts the soil microbial community composition, enzyme activity, C and N, and soil structure (Sarto et al., 2020b) (Fig. 3).

Fig. 3 Regulation of carbon stabilization in soil.

Regulation of soil organic carbon dynamics

As much as 20% of plant carbon remains in the soil as organic matter, sometimes referred to as 'humus.' Some of this carbon can remain in soils for hundreds and even thousands of years. The quantity of organic carbon in soil is a function of the amount of plant material entering the soil, the microbial decomposition rates of those residues, and the soil chemistry and mineralogy.

Soil C may be stabilized due to biochemical recalcitrance, chemical stabilization, and physical protection (Fig. 2). Any environmental factor that affects microbial activity influences the decomposition of organic material. These factors include soil water, temperature, pH, and O₂. Plant production and soil microbial activity are recognized as the biological processes governing soil carbon dynamics (Fig. 2). The amount of plant material produced is a function of plant species, as well as climate (temperature and available water) and nutrients. The composition of the plant material entering the soil is also a key regulator of microbial decomposition. Typical plant components include soluble sugars, hemicellulose, cellulose, and lignin, which vary in proportions between plant species, within plant species, and within plant organs. Of these components, lignin is the most difficult to degrade.

The quality of the carbon compounds (e.g., N content, C:N ratio, and lignin: N ratio) are important factors regulating decomposition processes (Fig. 2). The C:N ratio often serves as a guide to potential for decomposition; a ratio of more than 30 slows the rate of decomposition because of the lack of sufficient N for microbial growth; a ratio less than 20 provides sufficient N for microbial growth and allows decomposition to proceed (Robertson and Groffman, 2007). A ratio of 20–30 results in an equilibrium state between N mineralization and immobilization (Brust, 2019). Lignin content or lignin: N ratios are also used as a guide of organic matter degradability.

The organic carbon is transformed to greater biological recalcitrance as soil microorganisms process the C inputs from plant material in the course of microbial succession. Soil carbon may be stabilized because of its biochemical recalcitrance, e.g., lignin derivatives or melanin produced by fungi and other soil organisms. The rate of transformation is a function of temperature and soil moisture. As temperature increases, microbial activity increases; doubling for every 10 °C increase, ($Q_{10} = 2$). Soil-water content is also important; optimum microbial activity occurs at near 'field capacity,' which is equivalent to 60% water-filled pore space (Linn and Doran, 1984). As soils become waterlogged, decomposition slows and becomes less complete due to the lack of O₂. Peat soils are a result of these waterlogged conditions. As soils dry below 60% water-filled pore space, decomposition is also slowed due to water limiting conditions.

Soil structure plays a dominant role in controlling microbial access to substrates, and thus turnover (Fig. 2). Relatively labile material may become physically protected from decomposition by incorporation into soil aggregates. Disruption of aggregates, either by natural forces (freeze–thaw, wet–dry) or human activity (tillage) stimulates decomposition of the organic C protected inside the aggregates. One of the primary causes of soil organic C loss is tillage. The role of soil structure in the protection of soil organic carbon from decomposition is demonstrated by increased C mineralization in disrupted aggregates compared to intact aggregates. Cultivation of soils strongly affects the structural stability and reduces the amount of soil organic C, and this loss reduces the proportion of soil macroaggregates. No-till systems with crop rotation increase stabilization of easily degradable organic carbon via either physical protection or association with soil minerals (Arachchige et al., 2018).

Chemical stabilization of C refers to binding of organic C to clay surfaces or precipitation. Chemical stabilization by clay is regulated by clay type, pH, and other organics (Fig. 2). Clays that have a high adsorption capacity, such as 2:1 clays (e.g., montmorillonite), protect organic carbon to a greater extent than 1:1 clays (e.g., kaolinite), which have a lower adsorption capacity. Certain cations such as Ca, Al, and Fe are known to enhance the stabilization of organic carbon through cation bridges with clay surfaces. Clay type is an inherent property of soil and therefore cannot be directly manipulated as easily as the biological and physical mechanisms of stabilization. Inorganic forms of carbon in soil are the result of the equilibrium of CO₂ with water to form carbonic acid (H₂CO₃), bicarbonate (HCO₃⁻¹), and carbonate (CO₃⁻²) in the soil solution. Secondary minerals form in arid soils from the precipitation of Ca and Mg with carbonate. Dissolution of minerals also occurs depending on pH.

Composition of soil organic carbon

The most widely accepted theory on the formation of soil humus carbon is that, as plant material is decomposed by microorganisms, the altered compounds and new compounds synthesized by soil microbes polymerize through chemical or enzymatic reactions. Soil organic carbon is undergoing constant transformation. Typically, most models separate soil organic carbon into pools of organic matter that differ in composition and decomposability (Fig. 4). For example, the 'active' pool, comprised of microbial biomass and labile organic compounds, makes up less than 5% of the soil organic C. The slow pool usually makes up 20–40% of the total organic C, and the recalcitrant pool makes up 60–70% of the soil C. The microbial biomass, while a smaller proportion of the organic C in the soil, is the processing agent. The recalcitrant pool is material that is difficult to degrade and contains what is referred to in the historical literature as humic and fulvic acids – materials obtained by chemical fractionation procedures. However, a more recent view of recalcitrance is much more complex and is related to accessibility and ability of microbes to degrade complex carbon structures (Lehmann and Kleber, 2015). The active pool has turnover times in the order of months to years; the slow pool takes decades to turn over, while C in the recalcitrant pool takes from hundreds to thousands of years to turn over completely. However, 2–5% of the recalcitrant pool is degraded annually (Rice, 2006). Since the recalcitrant pool is generally in equilibrium in natural systems, the formation rate may equal the degradation rate (Rice et al., 2021).

Management

Most of the world's productive soils are now under cultivation. Historically, agriculture relied upon plowing the soil. In some cases, poor crop yields and removal of crop residues reduced the amount of organic material (carbon) to the soil. As a result, soil C content has decreased in many agricultural soils by as much as 50% over the last 50- to 100-years. A typical soil carbon-loss curve is shown in Fig. 4. Losses are rapid initially and then decline with time after the conversion to agriculture from native ecosystems. In recent decades, higher yields, return of crop residues, and development of conservation tillage practices have started to reverse the loss of soil carbon. These and other advancements in crop and soil management practices have the potential to increase soil C. Table 1 lists several practices affecting the soil's ability to sequester C. These practices can be grouped into three guiding principles: (1) minimization of soil disturbance; (2) maximizing plant production through nutrients and water availability; and (3) maximizing return of plant biomass (Fig. 5).

Intensive tillage, poor crop yields, lack of crop diversification, and excessive removal of crop residues have reduced C replenishment to the soil and thus negatively affected soil productivity. Tillage promotes disruption of soil aggregates, which exposes 'protected' carbon inside aggregates to microbial attack. In addition, tillage increases aeration, over-stimulating microbial activity, which results in the conversion of organic carbon to CO_2 . A reduction in tillage intensity, with no-tillage being the least disruptive in cropped soils, allows macroaggregate formation and reduces the degradation of soil organic C. *Minimum* or conservation tillage also conserves carbon in soil. Losses of soil carbon by erosion are reduced by conservation tillage. No-till can also enhance crop productivity (Daigh et al., 2018) and improve several soil properties, such as soil organic carbon (Nicoloso et al., 2018), bulk density (Blanco-Canqui et al., 2009), soil aggregation (Fabrizzi et al., 2009), and soil microbial community biomass (Bonini Pires et al., 2020). Organic waste and organic fertilizer, such as cattle manure, may replenish and maintain soil nutrient equilibrium, thus increasing nutrient status and crop yield. Organic amendments and crop rotation can increase soil organic carbon (Nicoloso et al., 2020).

Table 1 Management strategies for soil carbon sequestration.

Practice	Land use			
	Cropland	Rangeland	Forestry	Agroforestry
Soil Management	Reduced tillage intensity and residue retention, residue management, fertility, composting, improved water management, biochar application	Biodiversity/Perennial deep root, nutrient management, animal management, fire management	Reduce Deforestation, Afforestation and/or Reforestation, improved and sustainable forest Management, Fire Management, reduce conversion of savannas and Grasslands, reduce conversion and degradation of peatlands	woody biomass (including trees and woody shrubs) with crops, C allocation in different depths, synergism between species.
Crop Management	Crop varieties, crop rotation, cover crops, perennial cropping systems, integrated production system, crop diversification,

Fig. 5 Loss of soil carbon at the onset of cultivation for two locations in Kansas, Hays and Colby. Redrawn from Haas, H.J., Evans, C.E., and Miles, E.F.: 1957, Nitrogen and Carbon Changes in Great Plains Soils as Influenced by Cropping and Soil Treatment, USDA Technical Bulletin 1164, Washington, DC, US Department of Agriculture.

Cropping intensity affects the equilibrium level of soil organic carbon. Crop rotations and diversification can impact soil carbon levels by varying the amount and composition of the plant material added to the soil (Nicoloso et al., 2020; Bonini Pires et al., 2020). Crop rotation with forage crops can also, potentially increase P and K contents in the topsoil layer (Bassegio et al., 2015; Sarto et al., 2021). Cover crops capture nutrients such as phosphorus (P) and potassium (K) from deeper depths and store them in their aboveground biomass. The cover crop biomass will then be laid upon the soil surface, decompose and release nutrients through mineralization, making them available at the soil surface (Bassegio et al., 2015). In agriculture, high residue-producing crops such as corn, wheat, and sorghum tend to sustain or increase soil C. Elimination of summer fallow, a practice used in the Great Plains can increase soil C by providing more plant material on an annual basis. In those areas where sufficient soil water is available, double cropping is a viable practice, where two crops are produced per year. In more humid regions, winter cover crops are also a viable option for returning plant material to the soil. In grassland systems, perennial crops also tend to increase soil C because of the lack of tillage and the addition of organic C through root turnover. Integrated crop–livestock systems (ICLS) can increase agricultural sustainability and C sequestration potential. Sarto et al. (2020a) verified that the inclusion of *Eucalyptus* spp. to an *Urochloa* pasture added more C below 0.6 m depth, while *U. brizantha* increased C in the first 0.2 m, showing complementarity between the two species. However, the integration of trees into grass-dominated vegetation includes changes in above-and below ground productivity (Sarto et al., 2020c).

Those practices that directly affect plant production are also important in increasing soil carbon. Improved water management alleviates short-term water stress during the growing season, which improves the production of plant biomass and the return of plant material to the soil. In arid regions, irrigation can increase plant production and microbial activity. Water management also affects microbial activity, as discussed earlier. Fertility management eliminates nutrient limitations of plant growth. Proper management of nutrients supplies sufficient nutrients for the plant while minimizing the excess that could lead to degradation of the environment.

In agriculture, practices that increase soil organic matter include increase crop intensification, reduced tillage intensity and residue retention, crop management (e.g., improved crop varieties, crop rotation, use of cover crops, perennial cropping systems, integrated production systems (agroforest, intercropping systems), crop diversification, agricultural biotechnology), improved water management, manure or biochar application, maintained soil cover. Conservation agriculture combines the use of minimum soil disturbance, crop rotation (including cover crop), and residue retention to ensure minimal soil tillage intensity, maximum soil cover and increasing soil microbial community composition.

For grazing land, improved species, the addition of legumes, and fertilizer management can increase soil C in tame pastures. In native lands, proper grazing rotation and management of burning are strategies to improve soil carbon, especially for previously poorly managed grazing lands. Fire management includes the improved use of fire for sustainable ecosystem management of forested and savanna ecosystems, including wildfire prevention and prescribed burning. Prescribed burning is used to reduce the risk of large, uncontrollable fires in forest areas. Controlled burning is an effective economic method of reducing fire danger and stimulating natural reforestation under the forest canopy, and after clear felling, prevention of soil erosion and land degradation and is used in rangelands to conserve biodiversity and to enhance forage quality.

Table 2 Estimates of C sequestration potential of agricultural practices of US cropland.

Agricultural practice	(MTC ha ⁻¹ year ⁻¹)
Conservation Reserve Program	0.3–0.7
Conservation tillage	0.24–0.40
Fertilizer management	0.05–0.15
Rotation with winter cover crops	0.1–0.3
Summer fallow elimination	0.1–0.3

Adapted from Lal R, Kimble JR, Follett RF, and Cole CV (1998) The Potential of US Cropland to Sequester Carbon and Mitigate the Greenhouse Effect. Ann Arbor, MI: Ann Arbor Press.

Reducing deforestation and forest degradation supports the conservation of existing carbon pools in forest vegetation and soil by avoiding tree cover loss and disturbance. Reforestations are activities that convert land to forest, where reforestation applies to land that has previously grown forests and afforestation to land that historically has not supported forest. Reducing the conversion of grasslands and savannas to croplands prevents soil carbon losses by oxidation, and to a smaller extent, biomass carbon loss due to vegetation clearing.

Restoration of degraded soils and ecosystems offers a high potential for storing carbon in soils. Marginal croplands could be reverted to forests and grasslands. The Conservation Reserve Program of the US Department of Agriculture is designed to take marginal lands out of production (Table 2). Restoration of soils of mined land offers many opportunities for storing carbon in soil.

Conclusion

Soil carbon is a key pool of the global carbon cycle. The amount of carbon stored in soils is a function of the soil-forming factors climate, topography, soil type, time, vegetation. Human activity principally through agriculture and forest management influences soil carbon to the extent that we have lost about 50% of the carbon stored in soils globally. However, with improved agricultural management through increased plant productivity and forest management, we can restore the soil carbon. Soil carbon is the key component of soil status as it affects the soil's chemical, physical, and biological properties. With carbon as a critical component of soil health and offsets for climate change, interest in managing soils for carbon will increase interest and the management of soil carbon.

Abstract

Soils are a pivotal component in the global carbon cycle, while carbon storage in soils is a natural phenomenon involving organic carbon. Maintaining or increasing soil carbon levels is beneficial for many ecosystem services. Soil carbon is also a soil condition indicator and a key focus of several Sustainable Development Goals. This chapter describes the forms of carbon in soils, the quantification of carbon stocks and storage, the processes underlying the heterogeneous distribution of carbon stocks across the planet and their dynamics, land-use changes and practices that affect soil carbon stocks, as well as the socioeconomic benefits of soil carbon storage.

Glossary

Soil C content The C content in a soil is the quantity of C (organic or inorganic) in a soil mass. Total organic carbon (TOC) is expressed in gC.kg^{-1} soil.

Soil C stock The C stock is the quantity of C in a soil volume. In practice, it is expressed as a quantity of C related to a given surface area (tC.ha^{-1} or kgC.m^{-2}), for a given soil thickness.

Soil C storage Carbon storage represents the increase in a carbon stock over time, while generally being determined for a given soil, depth, land management change, duration and climate setting. It is expressed in $\text{tC.ha}^{-1}.\text{yr}^{-1}$. This storage can take a negative value when there is a loss of C. A distinction is made between potential storage, additional storage and effective storage (Fig. 3).

Land use Land use is the term applied to describe the human use of land. In the soil C stock framework, soils that bear forests, grasslands, cropland and soils of urban environments are differentiated under this term.

Agricultural practices For a given type of land use, agricultural practices refer to the techniques used for farming. They include, for example, vineyard grass cover cropping, establishment of temporary grasslands, intercropping, plowing or no-till farming, agroforestry, irrigation. . .

Key points

- Carbon occurs in different forms in soils: in living organisms, dead organic matter with particulate organic matter, organic molecules, and as inorganic carbon
- Soil carbon stock and soil carbon storage are different concepts: a carbon stock is quantified at a given date while its storage is quantified over a period of time

- The carbon stock distribution across the planet is heterogeneous, and complex biotic and abiotic processes underlie its dynamics
- For a given soil and climate, the largest stocks are found in forests and grasslands. In comparison, cultivated soils are carbon depleted
- Land-use changes and agricultural practices have a major impact on soil carbon stocks: they may have negative, positive or diverse effects on carbon storage, depending on climate and soil conditions
- Soil carbon storage provides socioeconomic benefits as targeted by five Sustainable Development Goals

Introduction

Plants fix atmospheric CO_2 through photosynthesis and incorporate it into the soil as shoot and root litter residues, and root exudates. This fixed carbon (C) remains soilborne as organic matter over variable periods of time before being largely converted back into CO_2 via the respiration of decomposer organisms. Soil organic C, estimated at more than 1500 billion tonnes, represents a major reservoir of the C cycle on continents. About half of this amount is present in the atmosphere (830 Gt), and about a third in aboveground plant biomass (550 Gt). Soils are at the heart of global carbon flows. Carbon sequestration in soils, i.e., the capture and storage of atmospheric carbon, contributes to climate regulation. In the context of increasing soil degradation and climate disruption, interest in soil organic carbon (SOC) has increased to the point where the topic emerged on the political agenda with the launch of the 4 per 1000 initiative at COP21 in Paris.

C occurs in soils as organic matter and inorganic mineral phases such as carbonates (e.g., CaCO_3). Inorganic C, especially present in soils developed on carbonate sedimentary bedrock such as limestone, generally follows reactive processes on long time scales. Although about 30% of soils worldwide contain inorganic C, its short-term dynamics and influence on organic C dynamics has barely been studied. Hence, only processes related to soil organic C will be discussed in detail hereafter in this chapter. In soils, the different types of organic matter that contain C include simple and complex biopolymers (~75%), particulate organic debris (including carbonized debris) (~20%), microorganisms (~2%), fauna (<1%) and very fine roots (<2%) (Fig. 1). These relative proportions are approximate and vary according to the climate, soil type, horizon, depth, land use and agricultural practices. C stocks are generally much higher in forests and grasslands than in croplands. As organic matter is essential for soil biological activity and health, increasing soil organic carbon stocks in croplands should contribute to food security and in turn limit global warming. In this chapter, we first define and explain how to measure soil C stocks and calculate C storage. The main mechanisms that control C storage are briefly presented. We then review agricultural practices and land use changes that favor or impair C storage in soil and finally discuss the importance of societal issues that arise from the SOC management strategies.

Quantification of soil C stocks and storage

The soil C stock is the quantity of C in a volume of soil. In practice, it is expressed as a quantity of C (measured in a soil sample) relative to a land surface area (tC.ha^{-1} or kgC.m^{-2}) in a given soil layer. To be representative of the real C stock in a studied plot, the soil samples being analyzed should be representative of the plot, with the sampling strategy adapted to the environmental heterogeneity. In highly heterogeneous soils, it is important to sample at fine plot scales across the surface (horizontal heterogeneity) and down the vertical profile. Storage (or destocking) represents the gain (or loss) of stock over a given time period. It is usually expressed in $\text{tC.ha}^{-1}.\text{yr}^{-1}$. Controversies regarding the quantification of C stocks and storage often arise due to ambiguities or lack of accuracy in the calculations. Therefore, we recall here: (i) the measurements needed (C content and soil density) to quantify soil C stocks, (ii) the calculation methods and possible corrections to be made, as well as (iii) the ranges of C stocks encountered in different types of soil at the global scale. We then detail the methods available to estimate soil C storage.

C content and density: Measurement parameters to calculate the soil C stock

To quantify a soil C stock, we have to measure: (1) the total soil C content (TOC), and (2) the soil bulk density, layer by layer of the soil profile, down to the depth considered in the stock calculation.

The TOC of a soil sample is the proportion of C (in mass) contained as organic matter in dry soil (dried at 105°C). It is expressed in gC.kg^{-1} of soil (gC.kg^{-1} is the International System unit, but % is also used, with $1\% = 10 \text{ gC.kg}^{-1}$). Unless otherwise specified, the soil mass is the dry mass at 105°C of 'fine soil,' i.e., soil sieved through a 2 mm mesh, without plant debris or coarse elements (gravel and pebbles, whose mass must be weighed independently). The organic C content of fine soil is usually measured directly, in a subsample of a few mg, by dry combustion with an elemental analyzer (after decarbonation of the sample if needed). The measurement uncertainty is about 0.1 gC.kg^{-1} . Other thermal and chemical methods exist that are often less precise or generate polluting products, e.g., the wet oxidation method ('Anne' or 'Walkley-Black'). Other indirect methods (visible and infrared spectroscopy) are under development (Allory et al., 2019). The latter are time-effective and inexpensive methods, but are not accurate enough (estimated uncertainty of 2.6 gC.kg^{-1} soil to 4.8 gC.kg^{-1}), while requiring complex calibration that is dependent

Fig. 1 Nature, size range and indicative proportions of organic matter in the <2 mm soil fraction. Organic matter accounts for less than 10% of soil constituents. The soil C stock primarily consists of dead organic matter molecules that mainly result from microbial activity. Adapted from Basile-Doelsch I, Balesdent J and Pellerin S (2020) Reviews and syntheses: The mechanisms underlying carbon storage in soil. *Biogeosciences* 17: 5223–5242.

on the pedoclimatic context. Fig. 2 shows TOC profiles measured in different soil types. Soil organic carbon (SOC) is vertically distributed, generally with a marked decreasing concentration gradient from the soil surface to depth. Soil C contents can range from 400 gC.kg⁻¹ soil in organic horizons at the soil surface to nearly 100 gC.kg⁻¹ soil in the first cm of the organo-mineral horizon, and down to less than 5 gC.kg⁻¹ at 1 m depth.

The dry bulk density (or apparent density) of fine soil (expressed in g.cm⁻³) is the second measurement parameter required to calculate C stocks. It is defined by the mass of dry soil (105 °C) divided by its volume. The soil volume can be deduced by the immersion of an undisturbed soil sample in water or directly obtained by harvesting samples of undisturbed soil in cylinders of given volume. Contrary to TOC, the soil density increases from surface to depth. The soil density is difficult to measure, especially in soils with a high proportion of coarse elements. This parameter is thus often not available in databases and may be estimated but this adds uncertainty to the C stock calculation.

C stock calculation

The organic carbon stock is the total amount of carbon contained in a given volume of soil. It is usually expressed, for a given depth, in kg per m² or in Mg per ha (t/ha is also used, with 1 kgC.m⁻² = 10 MgC.ha⁻¹ = 10 tC.ha⁻¹). It is calculated by multiplying the TOC by the mass of fine soil contained in the layer.

For a soil layer:

$$\text{SOC stock}_i = \text{BD}_i(1 - \text{CE}_i) \times \text{TOC}_i \times e_i \div 10 \quad (1)$$

For the soil, over the considered thickness:

$$\text{SOC stock}_n = \sum_{i=1}^n \text{SOC stock}_i \quad (2)$$

where i is the considered soil layer, n is the number of layer increments, TOC is the carbon concentration in fine soil (gC.kg⁻¹), BD is the bulk density (g.cm⁻³), CE is the proportion of coarse elements ($0 < \text{CE} < 1$), and e is the layer thickness (cm).

Soil C stocks can range from a few tonnes of C per hectare to several hundred tonnes per hectare. Fig. 2 shows the distribution of C stocks in soils (0–30 cm) worldwide. C stocks are highly variable and depend on the climate, topography, parent rock mineralogy, vegetation, soil use history and cultivation practices in agricultural soils.

A few noteworthy points when expressing or comparing C stocks in soils:

- A soil C stock is expressed in C, not in tonnes of CO₂ or CO₂ equivalent (tCO₂eq) as is the case for greenhouse gases.
- A soil C stock is a quantity of C for a given soil thickness. The soil thickness must be specified with the C stock measurement. In general, the soil C stock is quantified for a 0–30 cm soil layer (Fig. 2, IPCC reference thickness). Most historical research on C dynamics has been devoted to this soil layer and C stocks in the 0–30 cm soil layer are also usually taken into account in C dynamics models. Soil C stocks also account for deep soils (below 30 cm) but it is seldom measured.
- C stocks in soils under two land uses (or practices) must be rigorously compared for equivalent soil mass (Ellert and Bettany, 1995). The soil mass for a given soil layer thickness may differ between different land uses if the soil tends to be compacted, for example. Therefore, we recommend avoiding comparisons of C stocks at equivalent depth without correction for equivalent soil mass. It cannot be concluded that there is a greater soil C stock for a given land use if the difference noted is the result of the fact that a greater soil mass was taken into account. In practice, at a given depth, if the reference soil mass is the layer with the heaviest mass per unit volume, the correction applied for all cumulative increments is:

$$\text{SOC stock}_{n-\text{corr}} = \text{SOC stock}_n + \left(\text{TOC}_{n+1} \times (1 - \text{CE}_{n+1}) \times \frac{M_{n-\text{heaviest}} - M_n}{10} \right) \quad (3)$$

Here SOC stock_{n-corr} is the corrected cumulative SOC stock (tC.ha⁻¹) down to the depth of layer n; SOC stock_n is the uncorrected cumulative SOC stock (tC.ha⁻¹) down to the depth of layer n (Eq. 2); M_{n-heaviest} is the heaviest cumulative fine soil mass (g.cm⁻²); M_n is the cumulative fine soil mass (g.cm⁻²) and TOC_{n+1} is the fine soil carbon concentration of the underlying layer.

- Mulch or forest litter is a portion of the organic surface horizon that is often excluded from carbon budget calculations, although it is generally several decades old and can represent a significant portion of carbon stocks. H horizons in peatlands or wetlands and grasslands are also often inadequately considered.
- The soil carbon stock is at equilibrium when the inflow—through carbon inputs—is equal to the outflow—through mineralization, loss as dissolved organic carbon or erosion. The soil C stock will remain constant over time when the carbon stock is at equilibrium. Soil carbon is said to be in a steady state if the stock is at equilibrium and if the input flux does not vary over time.

Soil C storage

Carbon storage is the increase in carbon stock over time. It is defined for a given soil, climate, management change, soil depth and time period. It is expressed in $\text{tC}\cdot\text{ha}^{-1}\cdot\text{yr}^{-1}$ or $\text{kgC}\cdot\text{m}^{-2}\cdot\text{yr}^{-1}$. When the storage is negative, there is a C loss. The 4 per 1000 target represents a yearly increase of 0.4% of the C stock (Minasny et al., 2017). For instance, for a soil of $30 \text{ tC}\cdot\text{ha}^{-1}$ (0–30 cm), the target would be $0.12 \text{ tC}\cdot\text{ha}^{-1}\cdot\text{yr}^{-1}$ or $0.012 \text{ kgC}\cdot\text{m}^{-2}\cdot\text{yr}^{-1}$. Storage calculations are often performed over a 20 years period (Chenu et al., 2019).

When comparing two agricultural practices (e.g., Fig. 3, practices B and D), the additional storage related to the agricultural practice implemented in B is the difference between: (i) the carbon stock measured in soil after implementation of the practice over a given period (T_1 - T_2) (plot B), and (ii) the stock of the same soil under a reference practice (plot D) in the same common initial state at T_1 , without any change in practice over the same period (T_1 - T_2). The additional storage is thus defined for two practices, at a given site, and over a time period. A minimum of 5–10 years is generally required to measure the additional storage, but isotopic approaches are being developed to reduce these time lags (Jamoteau et al., 2021).

As for soil C stocks, we add a note of caution regarding several points pertaining to soil C storage estimation:

- The average annual C storage reflects the extent of storage over the observation time and should not be extrapolated to longer durations because the maximum possible storage potential is limited. Extrapolating the observed storage by a linear relationship entails a high risk of overestimation (Chenu et al., 2019).
- When carbon stocks (current or future) are not at equilibrium, the actual storage over time after a practice has been adopted and the additional storage resulting from the practice are separate data items (Fig. 3). Thus, for a situation where the SOC stock is decreasing due to past and current practices (plot C), it is possible that the additional storage following the adoption of a new practice will not fully offset the soil carbon stock downtrend. In this case, the additional storage is positive, yet the effective storage remains negative, which means that the soil continues destocking C, but at a slower rate. The carbon stock evolution trend expected under the current management method is called the 'baseline' (Fig. 3, scenario in plot D). Additional storage is always estimated as the deviation from baseline.
- For a given soil unit, the carbon storage potential is defined as the maximum gain in soil C stock that can be reached under a given climate and time period (Chenu et al., 2019). In practice, it is often hard to identify a reference soil so as to be able to accurately set the target C stock level.
- Storage and sequestration are two concepts slightly distinct although the underlying mechanisms are the same. Soil C storage considers only the increase or decrease of the C stock in the soil (the organic C accumulated from the soil is counted) while the notion of sequestration integrates the atmosphere together with the soil (we refer to the C of CO_2 subtracted from the atmosphere). Soil carbon sequestration is the net removal of CO_2 from the atmosphere that results from the transfer of

Fig. 3 Theoretical C stock trends as a function of changes in agricultural management practices: differences between carbon storage, additional carbon storage and potential carbon storage. Adapted from Pellerin S, Bamière L, Launay C, et al. (2019) *Stocker du carbone dans les sols français, Quel potentiel au regard de l'objectif 4 pour 1000 et à quel coût? Synthèse du rapport d'étude*, INRAE, p. 114.

atmospheric carbon into soil organic carbon compartments with slow turnover compared to a situation where the CO_2 would remain in the atmosphere. Olson et al. (2014) define soil C sequestration as ‘the process of transferring CO_2 from the atmosphere into the soil of a land unit, through plants, plant residues and other organic solids, which are stored or retained in the unit as part of the soil organic matter. Retention time of sequestered carbon in the soil (terrestrial pool) can range from short-term (not immediately released back to atmosphere) to long-term (millennia) storage.’

The soil C stock is dynamic

Carbon pools in soils are not inert carbon stocks. Soil carbon has a wide range of ages, from a few days to several thousand years old (Fig. 4) (Balesdent et al., 2018). The soil carbon stock is the sum of what remains from each past annual input. It depends on carbon influxes, biotransformation and the stabilization duration before the release of carbon from the soil, mainly as CO_2 produced by the respiration of decomposers. The processes that regulate carbon dynamics in soils are further described below (see Basile-Doelsch et al. (2020) for a detailed description).

Carbon inputs to soil

Organic matter entering the soil system is mainly synthesized by higher plants. It reaches the soil through the roots (dead roots or root exudates), shoot litter, and unharvested aboveground plant parts. The belowground input flux is considered to be the prime contributor to soil organic matter (Rasse et al., 2005). Rhizodeposition represents the contribution of carbon to the soil by living plants via roots. This may include root renewal, release of cells or tissues, macromolecules such as mucilage and extracellular enzymes, or small molecules, i.e., exudates. The rhizodeposition flux is estimated to represent 20–50% of the net root production (Jones et al., 2009). Belowground inputs are still largely unknown, highly variable, and constitute a definite but still relatively unexplored lever that drives soil carbon storage.

Diverse organic molecules are contained in and exuded by plants: cellulose and hemicellulose, lignin, pectin, protein from plant constituents, lipid from waxes and cuticles, tannin, and a multitude of other small molecules (sugar, organic acid) constituting root rhizodeposits (Kogel-Knabner, 2017). In comparison with a structural OM source, small molecules probably have a greater impact

Fig. 4 Meta-analysis of the carbon age distribution in 55 tropical grassland and forest soil profiles. At each depth, black curves indicate the proportion of carbon with an age of less than the specified time (i.e., 3 years, 10 years, etc.). Gray bands represent ± 1 standard error of the estimated mean. From Balesdent J, Basile-Doelsch I, Chadoeuf J et al. (2018) Atmosphere-soil carbon transfer as a function of soil depth. *Nature* 559: 599–602.

on carbon dynamics through their effects on microorganisms and organic matter (OM) mobilization via their priming effect (Keiluweit et al., 2015). Compared to plant OM, microbial products are enriched to different extents in other polysaccharides, lipids, proteins, amino-sugars, nucleic acids, chitin and a very diverse range of metabolites (Kallenbach et al., 2016). Soil organic matter is thus generated from all of these plant or microbial biopolymers or monomers.

Additional inputs may come from organic waste products (e.g., manure from poultry, cattle or pig, composed of mixtures of plant and microbial molecules or their monomers, as well as animal-derived organic compounds), compost and sewage sludge, or byproducts of incomplete combustion or pyrolysis (plant coal, biochar). Plastics may also be present in organic inputs. Moreover, soils may contain geogenic organic carbon, particularly when the parent rocks are organically rich, such as black shale which blackens the soil.

Organic inputs kickstart the soil food chain

Once in the soil, much of the organic matter feeds soil organisms that gradually degrade it. Biochemical reactions that occur during OM decomposition are mainly induced by microorganisms (fungi, bacteria, and archaea) that are soilborne or associated with soil fauna and herbivores. Recent studies have highlighted the close complementarity of all living organisms in the soil with regards to OM transformation:

- Macrofauna (earthworms, termites, ants, etc.) fragment the litter, incorporate it into the soil profile and mix the soil within the profile by bioturbation. Soil transit through the digestive tract of macrofauna (mainly earthworms) promotes contact between microbes and OM. Digestion alters the chemical structure of OM: many groups of soil fauna are thus recognized as stimulating microbial activity and soil organic matter biodegradation. Since some macrofauna organisms (like earthworms) feed on both soil and OM, they can also promote close contact between organic and mineral constituents and enhance the formation of organo-mineral complexes that stabilizes C in soil. Moreover, during bioturbation processes, soil fauna (e.g., earthworms, ants, termites, voles and moles) bury plant residue, gradually mix the soil, or move material between the surface and deep horizons.
- Micro- and meso-fauna (mites, springtails, collembola, tardigrades, protozoa, etc.) form a food web that regulates decomposing microorganisms, e.g., protozoa and bacteria-feeding nematodes tend to decrease the density of microbial populations (Trap et al., 2016).
- Microorganisms are the main drivers of OM chemical biotransformation. They represent the most taxonomically and functionally diverse component of living soil.

Organic matter biotransformation in soil: A carbon recycling business

Biotransformation processes in soil are chemical reactions catalyzed by enzymes produced by living soil organisms, particularly microorganisms.

Organic compound degradation reactions (so-called catabolic reactions) mainly involve hydrolytic or oxidative depolymerization processes (Lehmann and Kleber, 2015) that follow each other according to a continuum model (Fig. 5).

- Incoming plant compounds are mainly large molecules. Due to their size, their depolymerization first takes place outside microbial cells. Co-location between substrates and microorganisms at the microbial habitat scale is essential for the reactions to occur. Substrate-enzyme contact can take place by diffusion and advection of substrates and enzymes, or by microorganism growth (mainly for fungi) and mobility (mainly for bacteria). In addition, local environmental conditions (e.g., oxygenation, pH, water content, temperature) at the micrometer spatial scale must be favorable for microbial activity.
- The action of extracellular enzymes continues until smaller reaction products (sugars, phenolic compounds, amino acids, lipids smaller than around 600 Da) can be transported through the microbial cell membranes. The extracellular nature of reactions has several consequences. First, biodegradation has a high energy cost for organisms (e.g., enzyme transport through cell membranes) and cells have to invest C, N, P and S, whereas some compounds escape from the cells and are diluted in the soil solution or adsorb to other organic or mineral compounds. Small molecules resulting from biodegradation can thus aggregate via weak bonds (hydrogen bonds or hydrophobic interactions) with each other to form supramolecular assemblies (Sutton and Sposito, 2005) or with minerals to form organo-mineral associations (Kleber et al., 2015).
- Small molecular weight organic compounds (organic acids, sugars, amino acids) can be transported into the intracellular environment of microorganisms for further biotransformation. Oxidative degradation can continue until its ultimate stage when the elements are mineralized (CO_2 , NH_4^+ , H_2O , HPO_4^- , SO_4^{2-}). The entire biodegradation chain is shown in Fig. 5.

Unlike oxidative degradation, synthesis of new organic molecules from small organic molecular weight compounds occurs in microbial cells in so-called anabolic reactions. These new molecules, cellular components or excreted metabolites (e.g., organic acids, polysaccharides, extracellular enzymes) contribute to C stocks in soils. C incorporated by microorganisms and re-incorporated into soil OM is repeatedly recycled. A molecule quickly consumed by microorganisms does not necessarily mean that its C will be rapidly mineralized into CO_2 . The most biodegradable compounds have large long-term soil organic matter formation yields (Cotrufo et al., 2013). They display high reactivity that is easily stabilized by association with minerals. Relative to plants, microorganisms are the main producers of organic compounds that are sustainably stabilized through microbial growth, turnover, necromass formation and re-utilization (Kallenbach et al., 2016).

Fig. 5 Illustration of the soil OM biotransformation continuum model (Lehmann and Kleber, 2015). Organic matter enters the soil surface and deeper horizons in different forms. It is continuously degraded from plant and animal debris into tiny molecules by the decomposer community. 600 Da (approximately 1 nm) is roughly the maximum molecule size that can be absorbed by microorganisms. Simultaneously, the increase in the oxidation state of OM carbon increases the water solubility of the compounds. This also enhances their potential protection against further decomposition through increased reactivity with OM (supramolecular associations) and mineral surfaces (organo-mineral interactions) and incorporation into aggregates (aggregation). Solid arrows represent biotic processes and dashed arrows indicate abiotic processes. Adapted from Basile-Doelsch I, Balesdent J and Pellerin S (2020) Reviews and syntheses: The mechanisms underlying carbon storage in soil. *Biogeosciences* 17: 5223–5242.

The so-called ‘priming effect’ is another major process that may affect soil C dynamics and stocks. Here, the supply of complex decomposable substrates (from roots or exogenous inputs) provides competent microorganisms with the energy resources required to biodegrade stabilized OM through various mechanisms (stoichiometric decomposition, co-metabolism or nitrogen mining). Small organic acids of root exudates may also induce biodegradation of stabilized OM through abiotically-mediated priming effects (Bernard et al., 2022). Whatever the mechanisms, the rhizosphere is the main soil compartment concerned with priming.

Organic matter in close interaction with mineral constituents

Soil minerals account for over 90% of soil solid constituents (Fig. 1) and over the last decade organo-mineral associations have become recognized as a key factor in stabilizing soil organic matter. Mineral-associated organic matter (MAOM) is a critical soil nutrient reservoir that accounts for the majority of soil carbon (C) and nitrogen (N) in mineral soils (Kleber et al., 2015). MAOM has historically been considered a relatively passive reservoir of stable OM, but a growing body of research now points to the dynamic nature of mineral-organic associations.

MAOM is represented by aggregates at the micrometer scale (Fig. 5). MAOM aggregation affects the OM dynamics. Aggregates, especially microaggregates (<50 µm), are often used as fractions indicating the ‘degree’ of physical protection of carbon. Conceptual

models describe the C dynamics in the different aggregates by considering the formation-destruction cycles of the aggregates, but parameterizing these models is a complex endeavor.

Studies at the nanometric scale are necessary to gain insight into the mechanisms involved at the interface between mineral phases and organic molecules that drive C storage in soils. Mineral phases involved in organo-mineral associations can be classified into three main categories: well-crystallized minerals, short-range order phases and metallic monomers. Each category is associated with a distinct conceptual organo-mineral association model:

- Adsorption: organic molecules are adsorbed on the mineral surface of well-crystallized minerals (e.g., smectite, vermiculite or goethite). The adsorption model is conceptually the most intuitive.
- Coprecipitation: organic molecules are coprecipitated with short-range order phases or amorphous small polymers of Al, Fe and Si (e.g., allophane, ferrihydrites, amorphous Al hydroxides). They form a loose irregular 3D Al, Si, Fe network skeleton in which organic compounds are linked by various bonds (Tamrat et al., 2019). Co-precipitation would be the most common model in terms of the amount of stabilized C (Rasmussen et al., 2018).
- Complexation and bridging: organic molecules are bound to monomers (single ions). Al and Fe are the main metals involved in complexation in soils with a quite acidic pH. At higher pH, Ca dominates organo-mineral associations by cation bridging (Rasmussen et al., 2018). In both models, cations are surrounded by one or more organic molecules acting as stabilizers of the consortium of small organic molecules forming a so-called 'supramolecular aggregate' tertiary structure.

The existence of these different types of organo-mineral models should thus be considered when assessing MAOM dynamics. A further degree of complexity related to the binding energies should also be considered. Regardless of the model, the five following types of organic-inorganic bonds can be present: covalent bonding, electrostatic cation bridges, hydrophobic interactions, Van der Waals forces and H bonding. The binding strength varies greatly depending on the type of bond. These bonds between organic molecules and inorganic phases tend to slow down the OM degradation process, thereby disturbing the linearity of the biotransformation chain described in Fig. 5.

Part of the MAOM remains accessible to microorganisms but its mineralization is slowed down. The extent of this decrease in the mineralization rate depends both on the nature of the organic compounds and of the minerals. However, some MOAM compounds do not seem to be mineralizable by microorganisms. Thus, rather than using a binary terminology, suggesting that OM is, or is not, stabilized in organo-mineral associations, it would be more rigorous to use a stabilization gradient concept. This gradient is likely a key parameter that controls carbon dynamics in soils and its sensitivity to agricultural management.

Agricultural practices drive the C storage dynamics

Soil management practices affect soil C stocks by modulating the proportion of carbon-containing biomass returned to the soil and by altering the physical, chemical and biological properties of soils through direct or indirect actions (Fig. 6):

- physical modification of the soil surface horizon (tillage, compaction by the passage of machinery, etc.)
- export of plant C produced in the soil (harvesting, etc.)
- selection of crop species (generally these have low biodiversity)
- inputs of mineral products (fertilizers, pH regulators, etc.)
- inputs of exogenous organic matter (organic amendments)
- changes in the soil biological and microbiological activity (indirect effect of land management or use of biofertilizers).

Practices and land use changes with a negative impact on the soil C stock

Some land use changes are known to destock soil C: conversion of natural ecosystems to agricultural or pastoral systems (e.g., peatland drainage), or some agricultural practices (e.g., bare fallow) (Guo and Gifford, 2002). Land use change has resulted in the degradation of over a third of the world's soils (FAO and ITPS, 2015), with C contents greatly decreased compared to their historical values. All practices that maximize plant biomass export, thereby decreasing soil C inputs, prompt a decrease in soil C stocks.

The effects of practices must be assessed at the landscape level, since those implemented locally on a soil can impact the surrounding natural ecosystems. For example, in addition to the effects of climate change, treatments carried out to lower the pH of cultivated soils in Canada have favored the development of invasive earthworm species. These invasive organisms are colonizing boreal forests and causing the mineralization of C stored in the forest floor (Lejoly et al., 2021).

There is expected to be an increase in areas affected by salinity due to global change, with a projected concomitant effect on soil C stocks. Indeed, soil salinity reduces plant growth and thus C input while reducing microbial activity, thereby affecting the C dynamics. The SOC content of saline soils is generally low. Management practices such as phytoremediation, organic matter and biochar amendment have been proposed to rehabilitate saline soils by improving their structure, reducing the osmotic stress for soil organisms, increasing their C content and restoring their fertility.

Fig. 6 Different parameters that soil control C stocks: top—land uses; center—biotic and abiotic factors intrinsic to the soil; bottom—management practices that could be favorable or unfavorable to C storage, or have contrasting effects. Adapted from Basile-Doelsch I, Balesdent J and Pellerin S (2020) Reviews and syntheses: The mechanisms underlying carbon storage in soil. *Biogeosciences* 17: 5223–5242.

Practices and land use changes with a positive effect on soil carbon storage

Some land uses and management practices can increase soil C stocks by increasing C inputs or decreasing losses through the protection of soil C (Chenu et al., 2019). For example, land use changes, such as vegetated fallowing, natural state restoration, conversion of arable land to grassland, and practices that avoid bare fallows or increase crop diversification, can promote an increase in soil C stocks (Poeplau and Don, 2015).

In agricultural systems, C inputs can be increased by returning crop residues to the soil, adding exogenous organic matter (urban or agricultural waste compost, digestate from the methanization of agrifood residues used in the bioenergy sector, biochar), or by establishing a permanent soil cover. In grasslands, grazing increases C inputs compared to mowing. In forest, leaving slash scattered on forest floors increases C inputs as compared to clear-felling systems in which this slash is exported. In vineyard, grass-covered inter-rows favor C inputs. Combining several different land-uses on a soil increases the diversity and quantities of C inputs. This can be done, for example, by introducing temporary grass cover in crop rotations or by planting trees in croplands (agroforestry) (Cardinael et al., 2017).

Practices that increase primary production promote C inputs to the soil, either through belowground inputs, or through the aboveground portion that is not exported. Fertilizer application practices and crop selection can affect the soil C dynamics. For instance, the introduction of nitrogen-fixing legumes generates a soil nitrogen supply and can benefit primary production and C stocks. The organic form of nutrients improves the coupling of C, N and P biogeochemical cycles, and the plant nutrient uptake efficiency (e.g., Recous et al., 2019). Crop and intercrop plant selection could be a key way to maximize C inputs (Poeplau and Don, 2015). In particular, plants with large root systems or hyper-exudative roots increase belowground C inputs (see section [Carbon inputs to soil](#)), even if the aboveground parts are harvested and exported. Selecting crop varieties or grassland or forest species with deep root development could be an especially interesting opportunity to increase OM in deep horizons and store C throughout the soil profile.

Practices that limit soil C mineralization improve C stocks. These practices include the addition of mineral amendments, such as lime, that increase the soil pH, or of mining or quarrying waste to soils so as to promote organo-mineral associations, or OM protection within aggregates (Chenu et al., 2019).

Recent research has highlighted the importance of soil organisms in C storage as the activity of soil microorganisms and fauna may promote the formation of organo-mineral associations while safeguarding OM (see section [Organic matter in close interaction with mineral constituents](#)). Adopting and implementing practices that benefit soil organisms in the long term, such as reduced tillage, can thus promote C storage. Yet, paradoxically, soil fauna and microbiological activity contribute to both soil C storage and

mineralization (Lejoly et al., 2021). Research is still necessary to identify other practices that promote C protection through biological activity without increasing its mineralization.

Management practices that increase soil biomass inputs are not only beneficial for soil C stocks. There are many co-benefits, e.g., permanent plant soil cover reduces soil erosion, promoting the coupling of biogeochemical cycles (particularly of N and C) contributes to soil fertility (see section Agricultural practices drive the C storage dynamics). Meanwhile, the extent of the positive effect of the latter practices is very dependent on soil type and properties. Agricultural practices that enhance soil C stocks should therefore be implemented on the basis of local scientific studies focused on site-specific soil and ecosystem properties such as the pH, clay and initial soil C content. These are essential parameters to take into account regarding additional C storage in the form of organo-mineral assemblages (Cotrufo et al., 2019).

Practices with uncertain effects on soil C stocks

Reviews on soil additional C storage after a change of agricultural practices often show great variability in the values. It is likely that C input is the main factor in this variability, but a positive impact is not necessarily sustainable in the long term if the C losses induced become greater than the C input. Studies on the soil priming effect suggest that C addition to soil through readily degradable organic matter (plant residue, compost, digestate, etc.) can stimulate microbial growth and activity, although not increasing the C stock (Bernard et al., 2022). The antagonistic stocking and destocking effects are not yet fully understood and are dependent on the quality of the applied OM, soil depth and pedoclimatic conditions.

Tillage is a practice that has uncertain effects on carbon stocks since it is highly dependent on environmental parameters and soil type. Theoretically, no-till farming can help protect soil C by preserving aggregates and promoting the mixing of plant residues with soil mineral particles. However, the no-till impacts on carbon stocks can be transient or unquantified (Whitehead et al., 2018). Otherwise, no-till agriculture is recommended to control erosion—another source of soil C loss—so it has a positive effect on soil C stocks from this perspective.

Research on the effects of irrigation on C stocks have also produced conflicting results (Whitehead et al., 2018), because irrigation can jointly favor C input (decreased by drought) and C mineralization (slowed down by drought). Irrigation also modifies the plant root:shoot ratio (decreased by drought). Irrigation is assumed to have a positive impact in dry ecosystems and negative or no effect in humid climatic conditions (Whitehead et al., 2018).

Mineral N fertilizer is often applied to croplands and grasslands to increase the production of aboveground biomass, which is usually exported. Yet N fertilizer application can decrease carbon allocation to roots, and thus potentially decrease root carbon inputs to the soil. Since these belowground inputs are crucial for soil C stock accrual, mineral fertilizer application combined with plant export can have a negative effect. Whereas the direct effect of mineral N application on soil C stocks is uncertain, excessive use of mineral N may, in some cases, lead to pollution (nitrate and ammonia leaching) and N₂O emissions (Guenet et al., 2021), which has a global warming potential 261-fold greater than that of CO₂. Moreover, this practice consumes substantial fossil energy (fertilizer production and transport). It would therefore be essential to consider the global greenhouse gas balance of a given practice (e.g., through a life-cycle assessment), not only its impact on soil C stocks. The environmental, climatic and socio-economic repercussions of agricultural practices should be assessed.

Reforestation is often promoted to increase C stocks, but its ecological and socioeconomic impacts are more complex than they appear at first glance (Di Sacco et al., 2021). The tree species composition, stand density and pedoclimatic conditions (Cotrufo et al., 2019), as well as the economic contexts, vary markedly. Reforestation can also have negative impacts, including natural non-forest ecosystem destruction, loss of arable land which may in turn threaten food production, water cycle disruption, increase in invasive species and pollinator threats, decrease in C stored in vegetation and loss of soil organic carbon (Di Sacco et al., 2021). Reforestation must be planned at the landscape level, in a mosaic of land uses, but taking into account the overall needs of society and with the involvement of all stakeholders (business, government, NGOs, scientists, operational agents, landowners, farmers, citizens, etc.). When the economic conditions and the expected positive effects on the soil are satisfied, the reforestation program should favor a mixture of local species capable of mutualistic interactions while excluding invasive species. Safeguarding existing forests remains the priority.

Different urban soil uses and practices, such as unsealed or sealed soils in the vicinity of roads, parks and playgrounds, are poorly studied regarding their carbon stocks. Yet these soils can represent pools of organic carbon but they are highly variable and poorly quantified.

The benefits of soil C storage from the societal viewpoint

Soil organic matter (SOM) is pivotal factor with regard to soil functioning and properties, including soil fertility and biodiversity. SOM decomposition and mineralization contributes to nutrient recycling (N, P, K, etc.), which is essential for plant growth. SOM constitutes energy sources for heterotrophic soil organisms, helps maintain soil structure, contributes—along with clay minerals—to ion exchange capacity, thereby retaining pollutants and contributing to the underground water quality. On a global scale, soils capture more carbon than they release and are considered to be carbon sinks and contribute to climate regulation. Indeed, most of the terrestrial C (2000–3000 Gt C, Gt = gigatons or billions of tonnes of C) is in soils, 1500 Gt C of which occurs in the first meter of soil, compared to 830 Gt C in the atmosphere and 450–650 Gt C in plant biomass. As seen above, SOM and C

stocks are not homogeneous. Different organic pools, with different properties and dynamics, are involved in the soil C cycle. The most stable compartments associated with fine soil fractions (clay and fine silt) have a small role in nutrient cycling and agricultural production in the short term, but are more involved in long-term carbon stabilization (climate objective), in contrast to the particulate organic matter compartments (food security objective).

Maintaining organic matter levels in soils is beneficial for a range of ecosystem services that soil provides to our societies. Soil carbon and the land uses and management that affect its stocks are thus pivotal to many of the United Nations Sustainable Development Goals (SDG), including SDG #2 'Zero Hunger,' #13 'Climate Action,' #15 'Life on Land,' and #12 'Responsible Consumption and Production' (Fig. 7).

SOM losses, especially in dry regions or sandy soils, where initial levels are small, invariably results in the degradation of soil and associated functions, e.g., agricultural production. This often triggers a vicious degradation loop (Lal, 2004). Conversely, increasing SOM improves soil condition and fertility, thereby contributing to ecosystem and agroecosystem resilience and sustainability. The three international environmental conventions on Climate Change (UNCCC), Biological Diversity (UNCBD) and Desertification (UNCCD) have thus adopted the soil organic C stock as a land and soil quality monitoring indicator.

Knowledge of soil carbon stocks and dynamics is often considered to be a soil and agronomic research matter. This is no longer strictly the case and interdisciplinary research has been developed on all C fluxes and their implications for agriculture, energy and fiber production, socio-economics, and the climate. Increasing or maintaining soil carbon stocks is a global objective, but carbon storage can only be achieved locally through a multitude of soil uses and practices, and involve various stakeholders. These

Fig. 7 The benefits of soil C storage for soil functioning and ecosystem services and for the UN Sustainable Development Goals.

initiatives are sometimes associated with the transfer of organic resources (e.g., organic waste, biomass from crop residues, forage, mulch, forest products and manure) between different parts of a territory: such as from urban areas to periurban market gardening areas, from grazing areas to cultivated areas. Agricultural practices and land-use planning, such as sharing land for forestry, crop or livestock farming with their different extents of integration (e.g., agroforestry), have an impact on C fluxes and stocks. Programs aimed at increasing soil carbon stocks must therefore not only consider practices at the agricultural field level, but also the organization of the farm, territory, supply chains and markets to be effective, suitable and sustainable. Their multiple impacts, trade-offs between uses and technical, socio-economic and cultural limits, as well as the motives of the different stakeholders, must be taken into account.

Carbon storage in soils affects all activity sectors and can be considered at levels ranging from mineral particles that stabilize C in soils to large areas governed by public policies that regulate the use of agricultural, natural and urban spaces, and even international governance that can foster a public policy or funding in favor of soil C (Chevallier et al., 2020). Various disciplines (e.g., geography, agronomy, rural economics, sociology) are therefore necessary to understand and manage these C stocks and fluxes.

To reconcile the interests and constraints of each stakeholder with the C storage biophysical and technical parameters, socio-economic scenarios have to be developed to predict C stock variation patterns and their implications for people. These modeled biophysical, economic and sociological assessments are the basis for designing public policies adapted to the context. However, these assessments are still seldom performed.

Biophysical assessments concern C storage as well as all greenhouse gas emissions (especially CH₄ and N₂O) related to land use and management. There are still uncertainties regarding these complete greenhouse gas budgets in all contexts that research is striving to overcome through modeling. These uncertainties arise from the lack of data in some contexts. The diversity of soil type, climatic conditions and agricultural practices complicates the assessment of all impacts on C stocks and GHG emissions. In-depth characterizations of the context through both laboratory measurements and field surveys are therefore necessary to specify the local C storage potential. Factors responsible for the variability in these potentials must be identified to develop spatiotemporal extrapolation methods for monitoring and predicting C stock variation trends. These factors are, for example, climate, crop production, soil type, soil texture, and the amount of crop residues returned to the soil. C stock variation patterns must be evaluated both with and without changes in land use or agricultural practices to accurately assess the effect of the practice on C stocks and budgets (Fig. 3).

Therefore, it is essential to develop databases and methods that quantify the effects of changes in agricultural use or practice on soil carbon storage. Such a quantification and monitoring system would help to recognize and finance the service provided by agriculture to mitigate climate change. Indeed, one of the main challenges of the implementation of C storage or sequestration in contrasting environments is its social and economic acceptability and feasibility. This C sequestration objective cannot be disconnected from other issues and requires effort and investment at the same time as involving risk. Different parties could take on these investments and risks: the producer, the landowner or the society or community through subventions or guarantee mechanisms. Indeed, efforts to enhance C sequestration may not be attractive for a producer, who is not the landowner and who only benefits from the land in the short term. The benefits from a farmer's efforts are sometimes only perceptible in the medium or long term (e.g., degraded land restoration, agroforestry). Several studies have revealed that the technical potential for soil C sequestration may be high but its implementation limited by the absence of economic incentives to support the adoption of techniques conducive to C storage. In France, Pellerin et al. (2019) showed that additional SOC storage in French agricultural soils is limited to 0.66 MtC/yr in the absence of economic incentives, while its technical (or biophysical) potential is 8.43 MtC/yr. The cost of these economic incentives varies greatly between studies and countries, from around 5 euros per tCO₂ (Rakotovo et al., 2021) to around 100 euros (Soussana et al., 2019).

Assigning an economic value to SOC and bolstering the C market could be an effective incentive to improve SOC sequestration (Amelung et al., 2020). In agriculture, CO₂ certificates for sequestered soil carbon are being developed in recognition of farmer effort (Demenois et al., 2021). There are two main types of certification: those based on results achieved, i.e., quantification of GHG emission reductions (in CO₂ equivalents) and those based on the means implemented to reduce GHG emissions, i.e., recognition of the implementation of sequestering practices. The first type places the responsibility for implementing the practices on the farmers or foresters who initiate them, while the second type places the responsibility for implementing the practices on the certification authority. Implementation of the first type is more challenging since it requires actual C storage measurement and verification. It may be perceived as 'safer' and fairer but has little incentive. The second option seems simpler and may be more attractive if they are associated with a clear description of the specifications of the practices to be implemented. The second option also recognizes all ecosystem services that are enhanced by practice changes and C storage, not just their effects on GHG emissions and the climate.

Conclusion

Soil carbon storage is a natural phenomenon related mainly to organic forms of soil carbon. Atmospheric CO₂ captured by vegetation is integrated into the soil as organic matter, which represents 50–60% of all soil organic carbon. Although soils and vegetation emit CO₂, they serve as a C sink and host major stocks of carbon worldwide. Soils are the largest terrestrial reservoir of organic carbon in contact with the atmosphere. Soils and soil organic matter are key compartments in the global C cycle. Their

management may contribute to limiting greenhouse gas emissions, while also being crucial in combating desertification and enhancing soil biological activity and biodiversity.

Organic C present in soils in the form of organic matter has many roles (e.g., soil fertility, soil structure, retention of mineral elements and pollutants). Soil organic C is consumed by soil organisms and thus is a dynamic compartment that promotes soil biological activity. The organic matter mineralization that results from this biological activity releases nutrients that are essential for plant growth. The balance between organic matter stabilization and mineralization depends on processes that impact soil biological activity in the short or long term. These processes depend on the climate, soil type, land use and management practices. At the global scale, soil C stocks vary from 5 to 350 tC ha⁻¹ depending on pedoclimatic conditions and soil management practices. Soil use and management can lead to non-negligible variations in soil C storage. The eventual negative variations under cultivated soils are to avoid soil erosion and soil nutrient depletion. The positive variations, i.e., C storage, varies from 0 to about 2 tC ha⁻¹ years⁻¹, contribute to preservation of soil functioning, favor soil sustainable crop productivity and may help attenuate negative impacts of the global climate change.

There are major differences between current, additional and potential soil C storage. We have outlined the methods and highlighted potential pitfalls in measuring and calculating soil C stock and storage. Carbon stocks are regularly measured directly in soil samples and must be tailored to the spatiotemporal heterogeneity of the target soil, but such point measurements cannot be used to assess global patterns or be frequently repeated due to cost and time limitations. Spatial and temporal extrapolation methods are used to monitor and predict changes in soil C stocks in response to changes in land use and agricultural practices. Considering the interests and constraints of each stakeholder in the application of carbon storage techniques by developing socio-economic scenarios is essential. Prediction models and contextually appropriate public policies could be further designed based on biophysical, economic and sociological assessments.

Soil C data and knowledge on are sometimes partial or lacking, due to the heterogeneity of soils, varying climatic conditions, soil types and the diverse potential range of soil cover, uses and management. Long-term studies and data compilation are essential to gain insight into the drivers of the soil-C storage. Ongoing long-term, multidisciplinary studies are needed to better understand this complex issue. Nevertheless, initiatives geared toward boosting soils and soil C stocks must not be hampered or paralyzed by this complexity. Solutions that can be implemented are already available. In this chapter, we have reviewed land-use changes and practices that promote soil C storage and those that could lead to soil C loss. There are also practices whose impacts are uncertain because they depend on the pedoclimatic context. There is no single universal solution and choices to store or maintain C in the long term must be adapted to the local context.

Acknowledgments

We thank Sylvain Pellerin and Jerome Balesdent for discussions and exchanges during the INRAE 4 per 1000 study (Pellerin et al., 2019) which served as a guide in writing the first parts of the chapter. We are also thankful to the French network CarboSMS (Carbon Stabilization Mechanisms in Soil), which provided a framework for discussion and exchange on soil C storage. We thank Christian Hartmann, Florent Tivet and Aurélie Cambou, Pascal Podwojewski and Julien Fouché for providing images of soil profiles and associated data on the TOC concentration with soil depth. We thank Y. Yigini and M. Mainka for guiding us on how to use the latest version of the FAO Global Soil Organic Carbon Map.

Abstract

Soil organic nitrogen (N) is a paramount component of the terrestrial N cycle. Knowledge of soil organic N can inform a greater understanding of soil biogeochemical relationships, mitigate environmental degradation, and improve soil conditions in managed systems. This chapter provides an overview of soil organic N forms and classification, the cycling of organic N within soil, plant uptake, leaching, approaches to identify and quantify soil organic N, together with a discussion of how future research on soil organic N can be applied to the enhancement of agricultural productivity and sustainability.

Glossary

Amino acid Organic compounds that contain both amino (NH₂) and carboxylic acid (COOH) functional groups.

Biologically active N Nitrogen that is actively cycled by biogenic processes.

Monomer A simple molecule capable of covalent bonding with other monomers to form larger molecules.

Oligomer A molecule that consists of a few repeating monomers.

Oligopeptide A peptide comprised of a few amino acids.

Peptide A compound consisting of at least 2 amino acids linked by covalent bonds formed from the carboxyl group of one amino acid to the amino group of another, known as a peptide bond.

Polymer A macromolecule consisting of many repeating subunits.

Polypeptide An organic polymer consisting of many amino acids.

Reactive N Biologically active N. Includes all N forms except inert N₂.

Key points

- Soil organic N is a highly heterogeneous mixture containing many unique compounds.
- Depolymerization is the predominant pathway by which microbes and plants utilize organic N.
- The dynamics of soil organic matter are strongly linked to soil organic N transformations.
- Improved understanding of soil organic N cycling in natural and managed ecosystems may mitigate environmental issues.

Introduction

The terrestrial nitrogen (N) cycle includes soil, plant, and animal pools that contain relatively small amounts of biologically active N, in comparison with the substantial pools of inert N in the lithosphere and atmosphere. Nevertheless, the terrestrial N cycle and the transformations of N forms therein are integral to the global biogeochemical N cycle, as N is essential for life as a building block of DNA, RNA, chlorophyll, proteins, and enzymes. Nitrogen is commonly the nutrient most limiting primary productivity.

Despite the importance of N to all life, too much N in reactive forms triggers negative climatic and environmental effects. For example, over the past half century, reactive N inputs have accrued to unprecedented levels, associated directly with the addition of synthetic inorganic N fertilizer to agricultural soils and indirectly through increased atmospheric N deposition (Galloway et al., 2008). Consequently, the processing of augmented levels of reactive N has increased greenhouse gas production, the release of N in the form of N-oxides, and leaching losses of N to ground and surface water. Much of this N processing takes place in soils; as such, cycling of soil N, when functioning tightly, is a key ecosystem service that supports the terrestrial and global N cycles; but when producing excessive N losses, provides an ecosystem disservice.

Over 80% of N in soil is in the organic form, and the largest terrestrial reservoir of organic N is soil organic matter (SOM), which is a highly heterogeneous mixture of N-containing compounds that include proteins, amino acids, amino sugars, nucleosides, peptides, and some phospholipids (Warren, 2014a). Traditionally, research of the soil N cycle was largely focused on inorganic N forms (ammonium $[\text{NH}_4^+]$ and nitrate $[\text{NO}_3^-]$). This was motivated by the prominent role of the inorganic N in agricultural management and thus the perceived dependency of agricultural production on this N pool (Näsholm et al., 2009). However, a paradigm shift in our understanding of the terrestrial N cycle has questioned the common assumptions underlying N management that plants *solely* utilize inorganic N sources, and instead are capable of utilizing a wide variety of N sources, including organic N forms, in addition to inorganic N (Schimel and Bennett, 2004). Thus, the soil N cycle is now viewed as being driven by the depolymerization of high molecular weight organic N to bioavailable organic N monomers that can be directly utilized by microbes and plants, in addition to utilizing soil inorganic N. For agronomically important plants, this may present an opportunity to transition away from the currently exclusive reliance on synthetic N fertilizers (Farzadfar et al., 2021). Further, significant improvements in our understanding of the nature of SOM, which is a pillar of the soil condition and an important component of climate change mitigation, have highlighted the importance of organic N for primary productivity and as a component of persistent, mineral-associated organic matter (Cotrufo and Lavelle, 2022; Lehmann and Kleber, 2015). As such, a greater understanding of organic N pools and cycling is key to better understanding the functioning of natural ecosystems, improved management of agricultural systems, and stabilization of SOM stocks.

Soil organic nitrogen forms and properties

Soil organic compounds are described on a continuum from intact organic material to large biopolymers, small biopolymers, and monomers (Lehmann and Kleber, 2015). As a component of SOM, most soil organic N is in amide bonds, the bonds present in protein molecules, with a lesser proportion in amine and heterocyclic N bonds. The vast majority (>90%) of soil organic N is sorbed onto soil minerals or protected within aggregates, whereas a small portion of organic N (1–4%) exists as a component of particulate organic matter (POM), which is a transitory pool in the decay continuum of SOM (Warren, 2014a). Dissolved organic nitrogen (DON; 0.1–2%) represents the soluble N in the soil solution, the exact chemical composition of which is controlled by soil organic N sources and varies with soil type, land use, and environmental conditions.

Functional and ecological differences in DON molecules are directly or indirectly related to molecular weight. Based on molecular weight, DON can be broadly divided into three major classes: high molecular weight (HMW), medium molecular weight (MMW) and low molecular weight (LMW) (Fig. 1). The LMW fraction of DON is cycled within hours while the MMW and HMW fractions are cycled much more slowly (~days to months) (Warren, 2014a).

Fig. 1 The approximate distribution of soil organic nitrogen (N). MAON: mineral associated organic nitrogen; POM-N: particulate organic matter nitrogen; DON: dissolved organic nitrogen; HMW DON: high molecular weight dissolved organic nitrogen >100 kDa; MMW DON: medium molecular weight dissolved organic nitrogen from 1 to 100 kDa; LMW DON: low molecular weight dissolved organic nitrogen <1 kDa. Adapted from Warren CR, (2014a) Organic N molecules in the soil solution: What is known, what is unknown and the path forwards. *Plant and Soil*, 375(1): 1–19.

The HMW class is composed of oligomers and polymers of amino acids with molecular weights >100 kDa. Most soil DON falls into the HMW class, of which proteins comprise the majority; up to 99.5% of amino acids in soil are contained in HMW polymeric N compounds, such as proteins and peptides. The HMW class also includes smaller amounts of bacterial cell wall-derived peptidoglycan and fungal-derived chitin, the composition of which varies between species. Typically, peptidoglycan is composed of *N*-acetylglucosamine and *N*-acetylmuramic acid cross-linked by peptide bonds of 3–5 amino acids attached to *N*-acetylmuramic acid (Fig. 2). Polymeric linkages of *N*-acetylglucosamine are the basis of chitin.

The MMW class is the smallest pool of DON, consisting of peptides and proteins of molecular weights ranging from 1 to 100 kDa. The LMW class is comprised predominantly of protein amino acids, with smaller quantities of non-protein amino acids, quaternary ammonium compounds (QACs), amino sugars, purine and pyrimidine bases, nucleic acids, and short oligopeptides weighing <1 kDa (Fig. 3).

As the major component of the LMW class, all 20 protein amino acids have been identified in the DON fraction of soils, and common non-protein amino acids include gamma aminobutyric acid (GABA), citrulline, and ornithine. Amino acids can be present as *L*- or *D*-enantiomers, i.e., as stereoisomers that are mirror images of each other, based on their atomic arrangement. The *D*-amino acids are less abundant compared to their *L*- counterparts, however *D*-amino acids can occur naturally in bacterial cell walls, microbial metabolites, antibiotics, eukaryotic biomass, and from the biotic or abiotic racemization of *L*-amino acids. Compared to their *L*- counterparts, *D*-amino acids may undergo slower mineralization rates in soil.

Also abundant in the LMW pool are QACs, which include proline, proline betaine, ectoine, hydroxyectoine, and hercynine. Most QACs are product of microbial synthesis and may account for 1–28% of non-peptide compounds in the LMW organic N class.

Soil organic nitrogen cycling

As a component of SOM, soil organic N is the largest reservoir of N in the terrestrial biosphere; therefore, its cycling is crucial for the global N cycle. Soil organic N inputs are determined by primary productivity, mainly entering the soil in the form of particulate organic matter (POM), via inputs of plant litter, rhizodeposits, animal excreta, and microbial turnover. Leaching from surface litter and root exudation, as well as small amounts of pyrogenic organic N in fire-affected systems can also contribute as DON (Knicker, 2011). The largest input of organic N to soil is proteinaceous material, via the addition of above and belowground plant material and microbial residues (Greenfield et al., 2020). Plants and microbes contain thousands of diverse proteins, which differ from one another in terms of solubility, charge, size, and structure. A smaller fraction of the organic N input to soil includes other polymeric compounds that are of microbial origin, such as peptidoglycan and chitin (Liang et al., 2019). In soil, organic N is subject to the following processes: (1) depolymerization from HMW to LMW DON compounds, (2) microbial cell uptake, (3) mineralization to inorganic N, (4) incorporation into persistent SOM, (5) direct root uptake, and (6) DON leaching (Fig. 4).

Fig. 4 A simplified soil organic nitrogen cycle. *a*: depolymerization; *b*: microbial uptake, i.e., immobilization; *c*: mineralization; *d*: plant uptake; *e*: microbial turnover and necromass formation; *f*: leaching; *g*: protection of organic nitrogen by various mineral associations; *h*: inputs of organic N, i.e., leaching from aboveground plant litter; *i*: root contributions to soil organic N via cell sloughing, cell lysis, and exudation; *j*: desorption of organic N from mineral surfaces.

Depolymerization and microbial cycling of dissolved organic nitrogen

In general, HMW polymeric material is not readily available for plant and microbial uptake; although some plants may have the capacity to take up HMW organic N compounds, it is not a main pathway of N acquisition (Paungfoo-Lonhienne et al., 2008). Instead, depolymerization of HMW organic N forms to LMW polymers and monomers is the predominant pathway by which plants and microbes can assimilate organic N. The conversion from polymeric organic compounds into bioavailable N regulates N availability in the ecosystem, therefore, depolymerization of HMW organic N is often referred to as the 'rate-limiting step' of the soil N cycle, as depolymerization is central to the provision of bioavailable N (Schimel and Bennett, 2004). However, recent experimental results challenge this paradigm, suggesting that it is not protein depolymerization but instead the rate of protein supply from plant and microbial turnover in soils that controls N availability in soil (Greenfield et al., 2020).

Depolymerization of protein is facilitated by extracellular protease enzymes, which are produced and released by bacteria, fungi, and plant roots. Based on their mode of action, proteases can be classified into exopeptidases and endopeptidases. Both groups facilitate the breakdown of proteins via hydrolyzation, but exopeptidases cleave peptide bonds adjacent to the amino or carboxy termini of peptide chains to produce individual amino acids, whereas endopeptidases cleave peptide bonds present on the inside of the polypeptide molecules, forming oligopeptides (Fig. 5). Importantly, it is sometimes assumed that complete depolymerization of proteins to amino acids occurs, however, evidence suggests that enzymatic degradation of proteins can produce similar quantities of peptides and amino acids, and both can act as an N source for microbes (Warren, 2021). Other HMW organic N, including nucleic acids, cell-wall derived peptidoglycan, and fungal chitin must also undergo depolymerization prior to being utilized as an N source by microbes, albeit at much lower rates than protein-derived peptides and amino acids. Extracellular enzymes catalyze the cleavage of peptidoglycan to muropeptides and muramic acid, chitin to *N*-acetyl-glucosamine and glucosamine, and nucleic acids to individual nucleotides.

After depolymerization of HMW organic N to LMW organic N, compounds can be directly assimilated by microbes, a process that is referred to as the direct route. Conversely, the low C:N ratio of peptides and amino acids can lead to mineralization and release of NH_4^+ into the soil solution, thus becoming available to microbes and plants, or removed by exchange sites on soil minerals and SOM. In processing the available NH_4^+ , microbes may carry out mineralization-immobilization-turnover (MIT), or nitrifying bacteria may oxidize NH_4^+ to NO_3^- , which can then be used as a terminal electron acceptor by denitrifying bacteria and reduced to gaseous nitrogen oxides and dinitrogen and lost to the atmosphere. The quantitative and relative importance of the direct vs. MIT routes of NH_4^+ use during decomposition is determined by factors such as the form of N available, the source of C, and the availability of N relative to C (Geisseler et al., 2010). Overall, cycling of LMW organic N occurs rapidly in soil, leading to small pool sizes of biologically available DON but significant fluxes that can turnover multiple times per day in some ecosystems.

Notably, the rate of soil organic N cycling can be altered by the priming effect, which is the short-term acceleration or retardation of SOM mineralization in response to fresh inputs of C or N to the soil, such as litter, rhizodeposits, or N fertilizer (Kuzyakov et al., 2000). The precise mechanisms underlying this phenomenon are still debated, however, evidence suggests that multiple microbially-driven mechanisms are simultaneously acting in soils leading to observations of the priming effect (Daly and Hernandez-Ramirez, 2020). The N mining hypothesis posits that the priming effect is a response of the soil microbial community to N-limitation after fresh C inputs to soil, thus the acceleration of SOM mineralization is a strategy to liberate assimilable organic N forms for microbial utilization. Conversely, the stoichiometric decomposition hypothesis suggests that the priming effect is due to stoichiometric C and N needs of microbes being met by exogenous inputs, which results in the temporary enhancement of microbial activity and amplified depolymerization of organic N forms (Chen et al., 2014). Therefore, the priming effect is a critical consideration for depolymerization and the stability of SOM, as this enhancement in microbially-mediated turnover can enhance N loss from the soil system.

Soil organic matter persistence

The dynamics of SOM are strongly linked to soil N transformations, as organic N is a major component of SOM and subject to microbially-mediated transformations. When considering the role of microbes in organic N depolymerization, it may be considered paradoxical that microbial cycling of organic N is simultaneously critical for the formation and persistence of SOM. However,

Fig. 5 Depolymerization of protein via hydrolyzation of peptide bonds by *exo*- and *endo*-peptidases.

Table 1 Factors controlling the incorporation of microbially-derived N-containing organic matter into the persistent SOM pool.

Factor	Importance
C: N ratio	Substrate Affects the efficiency (i.e., anabolism vs. catabolism [or assimilation vs. respiration]) and quantity of microbial processing. High throughput of better quality substrate (i.e., materials with a low C:N ratio) can result in a greater mineral-stabilization of SOM due to enhanced microbial residue production
Microbial community structure	Microbial processing Affects the efficiency and quantity of microbial processing and thus the formation of persistent SOM. Microbial communities with high substrate use efficiency may produce greater amounts of N-rich necromass, a primary component of stable OM
Edaphic and environmental conditions	Conditions that favor greater microbial activity will allow greater production of microbially processed OM and therefore may enhance the production of N-rich necromass
Mineralogy	Adsorption Clay minerals play a role in OM persistence. The large surface area of clay particles leads to a greater number of charged sites and thus binding sites for microbial by-products. The net negative charge, small pore spaces, and swelling nature of some phyllosilicate clay minerals can further increase this capacity
Protein size and structure	Affects adsorption to mineral surfaces. Larger organic N compounds (ex. proteins) may have several sites for binding to minerals which can enhance bonding strength and limit active sites for enzyme attachment. Conversely, larger proteins may show increased folding and result in fewer bonding sites
pH	Affects the surface charge of the minerals and the degree of ionization of proteins. The prevalence of ligand exchange, a strong bonding mechanism, increases as pH decreases between proteins and Fe-oxides and Al-silicates
Antecedent OM	The presence of previously sorbed OM can decrease further adsorption capacity if attachment sites are saturated.
Microaggregate formation	Spatial separation Occlusion within aggregates or within small pores may protect SOM from microbial decomposers
Soil depth	Reduced diffusion of water and nutrients to microbial decomposers at depth limits microbial processing of SOM

microbially-derived residues are the main contributor to SOM via biomass turnover and necromass accumulation. Overall, more than 80% of soil organic N is estimated to originate from microbial sources (Hu et al., 2020). Soil microbes contribute a source of chemically diverse, recalcitrant organic matter resulting from anabolic processes that incorporate N into microbial cell walls. Incorporation of microbially-derived organic matter into the persistent SOM pool—the pool that is long-lived and resistant to degradation—is dependent on the substrate composition, microbial community characteristics, the stabilization of organic matter by soil minerals via sorption to cation exchange complexes, and the formation of organo-mineral associations (Hu et al., 2020; Lehmann and Kleber, 2015) (Table 1).

Adsorption of organic N containing molecules onto mineral surfaces reduces their susceptibility to degradation by blocking the attachment of extracellular enzymes, as well as retarding their transport in soil solution and thus reducing their availability (Bingham and Cotrufo, 2016). Absorptive capacity differs between soil environments, dependent on mineralogy, pH, and DON composition. Soils high in phyllosilicate clay minerals and Fe and Al oxides increase the number of binding sites for organic N, whereas pH can alter the charge present on mineral surfaces. In low pH environments, Fe and Al oxides are dominant and predominantly positively charged, which results in bonding via cation exchange. At neutral pH, phyllosilicate clays are negatively charged, and cation bridging becomes more prevalent (Bingham and Cotrufo, 2016). Organic N may also be protected by incorporation within soil aggregates or physical separation in occluded soil pores that are too small for microbes or their enzymes to enter.

Plant uptake of soil organic nitrogen

Previous research into plant nutrition mainly focused on plant reliance of inorganic N forms, i.e., NH_4^+ and NO_3^- , despite organic N comprising up to 90% of the soil N pool. However, an updated understanding suggests that plants, including those of agronomic importance, can take up and utilize a wide variety of organic N forms, including amino acids, peptides, and even proteins, albeit in small but significant amounts (Farzadfar et al., 2021). Notably, organic N compounds play a particularly important role in plant nutrition in N-limited ecosystems such as the tundra or boreal forest, where inorganic N levels are too low to support plant productivity as observed, suggesting that amino acid uptake is a feature many different species possess (Nordin et al., 2004; Persson and Näsholm, 2001).

Like inorganic N, plant acquisition of organic N requires direct contact with roots, with or without the aid of mycorrhizal associations (Näsholm et al., 2009). Direct contact between roots and organic N forms can occur via mass flow, diffusion, and root interception, with diffusion being most significant in the rhizosphere. Plant uptake of organic N compounds is an energy-driven process facilitated by both high and low affinity transport systems located in the plasmalemma, which require the plasma membrane H^+ -ATPase to generate a proton motive gradient. Numerous amino acid and peptide transporters in various species have been identified to date, the former of which differ in their specificity for neutral, basic, or acidic amino acids (Tegeeder, 2012).

Once inside the root cells, organic N compounds are used for biomass and energy production. Specifically, organic N compounds are catabolized in the cytosol of plant root cells to release NH_4^+ and intermediaries such as glutamate. Cytosolic NH_4^+ is used to synthesize glutamine which is then transported into the plastid and assimilated by the GS/GOGAT cycle, producing glutamate. Likewise, the glutamate generated in the cytosol (via catabolism of organic N) enters the GOGAT cycle within the plastid. Subsequently, glutamate is subjected to further aminotransferase reactions to produce other amino acids or is cycled back to glutamine by cytosolic glutamine synthetase and plastidial glutamine synthetase. Similarly, any NO_3^- that is transported into the cytosol of plant root cells is reduced to NO_2^- , transported into the plastid for further reduction to NH_4^+ , and thereafter enters the GOGAT cycle.

Because the rhizosphere is a zone of intense competition for resources, the relevance of organic N as an N source for plants has been questioned, namely because microbes tend to be more efficient at amino acid assimilation due to their high uptake capacity (Kuzuyakov and Xu, 2013). The ability to take up organic N has therefore been suggested as a mechanism to recapture amino acids passively “leaked” from root cells, as opposed to organic N acting as a significant nutrition source for plants (Jones et al., 2005). However, plants have several strategies which may allow them to compete for organic N resources in soil. These strategies include a longer life span than microbes, which release previously bound organic N compounds thus maintaining a temporal niche differentiation, mycorrhizal associations, and root-derived proteases (Kuzuyakov and Xu, 2013).

Certain plants from a variety of ecosystems form associations with particular mycorrhizal fungi, which facilitates the uptake and utilization of organic N forms. The uptake, transformation, and transfer of organic N to plants by mycorrhizal fungi is multi-step process, beginning with the depolymerization of HMW organic N to LMW forms. Ectomycorrhizal and ericoid mycorrhizal fungi can produce a suite of exoenzymes that depolymerize HMW organic N to LMW compounds (Moreau et al., 2019). However, arbuscular mycorrhizal fungi (AMF), which form mutualistic relationships with approximately two-thirds of all land plants, have poor exoenzyme production capability but may increase plant organic N acquisition by hyphal proliferation and cooperation with other soil microorganisms from organic N enriched hotspots in soil (Jansa et al., 2019). Assimilation of organic N by mycorrhizal fungi is facilitated by membrane transport proteins that are general enough to take up several amino acids, or specific enough to target one type of amino acid. Once acquired, the compound may require transformation prior to transfer to the host plant, which requires energy and resource investment by the fungi. The degree to which transfer of organic N from fungi to host plant occurs depends on complex interactions, cost-benefit relationships, and plant and fungal species.

Plants may also increase organic N acquisition by secretion of root-derived proteases, namely in the form of root-bound proteases (Adamczyk, 2021; Greenfield et al., 2020). Enhanced proteolysis on the root surface may enhance plant organic N uptake by reducing competition with microbes, however, the importance of this process for N nutrition is not fully known (Greenfield et al., 2020).

Dissolved organic nitrogen leaching

Leaching of DON is a central pathway of N loss and therefore is an essential component in the soil organic N cycle. Excess leaching of DON into surface waters and drinking water reservoirs can lead to eutrophication, acidification, and potentially pose risks to human health (van Kessel et al., 2009). Organic N leaching occurs as water moves through the soil, but, as opposed to inorganic N losses which are controlled by biological N demand, the losses of organic N are controlled by the depolymerization rates of DON and solubility (Ros et al., 2009). Most DON that is lost to leaching is HMW DON. Because of the HMW form, this loss may not be considered a major loss of bioavailable N for plant and microbial utilization, however, leaks can be large even under extremely N-limited conditions (van Kessel et al., 2009).

In forest ecosystems, our understanding of the N cycle has long included losses due to DON leaching, which can exceed losses of NO_3^- , especially in undisturbed forested ecosystems where DON leaching can account for up to 95% of total dissolved N lost (Perakis and Hedin, 2002). Notably, large leaching losses of DON in forests might explain persistent N limitation in these ecosystems. Conversely, due to the large solubility and mobility of NO_3^- in soil, studies of leaching losses in agroecosystems are often focused on inorganic N and neglect organic N leaching. However, an updated understanding suggests that DON leaching can represent a significant leak of N from the soil system in agroecosystems. Namely, DON leaching can account for up to one-third of total N lost to leaching, (van Kessel et al., 2009).

Sampling, identification, and quantification of organic nitrogen

Quantification of total organic nitrogen

Total organic N in solid soil samples may be determined by the Kjeldahl method or the Dumas method. In brief, the Kjeldahl method digests samples with the aid of a catalyst at high temperature in sulfuric acid (H_2SO_4) then analyzes the distillate NH_4^+ by titration. The total Kjeldahl-N pool usually includes soil soluble NH_4^+ -N in addition to the organic bounded N groups. If the strongly fixed NH_4^+ in minerals is also desired, hydrofluoric acid (HF) may be used in place of H_2SO_4 (Leinweber et al., 2013). For the Dumas method, samples are combusted at very high temperatures in pure oxygen, which releases nitrogen oxide gases that are reduced to N_2 and quantified using a thermal conductivity detector. This provides total N in the sample; organic N must then be determined by subtracting total inorganic N from total N. Inorganic N (i.e., NO_3^- , NO_2^- and NH_4^+) is determined by reacting a subsample with specific reagents for target analytes and followed by ion chromatography or colorimetric analysis. If removal of

fixed NH_4^+ is required, pre-treatment with a strong oxidizing agent such as potassium hypobromite (KBrO) or potassium hydroxide (KOH) is needed (Leinweber et al., 2013).

Sampling dissolved organic nitrogen

Obtaining a sample of organic N from the soil solution can be done ex-situ, via extraction followed by centrifugation or filtration, or in-situ, via microfiltration or microdialysis. Significantly, some literature distinguishes between samples obtained via extraction and those obtained from in-situ methods, as extraction methods also may include soluble organic N compounds that are sorbed to soil particles. Therefore, ex-situ procedures obtain samples of total soluble organic N (SON), whereas in-situ techniques capture DON in the soil solution alone.

Bulk soil samples can be extracted using water or salt solutions including KCl, K_2SO_4 , BaCl_2 , NH_4Cl , NaHCO_3 . The analyte can then be separated from soil using either filtration or centrifugation. This method is ideal for dry soils, but recovery of SON can vary dependent on soil type and extraction procedure. Alternatively, samples can be directly centrifuged to separate the solution from the solid phase. This method requires field moist soils, and like extraction, involves disruption of the soil structure, which may result in deviations between results and actual SON concentrations available in soil.

In-situ methods, such as microfiltration, use suction lysimeters with a semi-permeable membrane that can be installed in soil to collect samples of pore water via mass flow after the application of partial negative pressure. These samples require less soil disturbance compared to their ex-situ counterparts; however, samples can be biased towards larger pores and adsorption of organic compounds to the lysimeter membrane can reduce concentrations in the solution (Jones and Willett, 2006; Warren, 2014b). Microdialysis is a technique that permits sampling of solutes via diffusion, which is driven by the concentration gradient between a perfusate and the soil solution. In this method, a microdialysis probe with a semi-permeable membrane is inserted into soil. Soil solutes then diffuse through the probe membrane into the perfusate which flows at a constant known rate, and which is then continuously sampled (Buckley et al., 2020).

Fractionation, identification, and quantification of organic nitrogen compounds

Several chromatographic methods can be used to separate and quantify organic N compounds in the soil solution, including gas chromatography–mass spectrometry (GC–MS), liquid chromatography–mass spectrometry (LC–MS), capillary electrophoresis–mass spectrometry (CE–MS), pyrolysis–gas chromatography mass spectrometry (Py–GC–MS). Each of these methods combines different compound separation techniques with mass spectrometry (MS) for the profiling of charged molecules, and have detection limits capable of identifying various organic N classes in soil solution when a pre-concentration process is applied to samples prior to analysis. Namely, combining a separation technique prior to MS allows for the separation and identification of ions with the same nominal mass, but different exact mass, as well as the identification of structural isomers. The drawback of these methods is that no single analytical platform provides comprehensive identification and quantification of all organic N compounds.

Compounds must be volatile for analysis by GC–MS, which is not applicable for several organic N molecules (i.e., QACs, oligomers, and polymers). As such, this method is largely limited to the identification of amino acids. If using LC–MS, neutral and anionic compounds can be analyzed, but not polyamines. In contrast, CE–MS can analyze cationic compounds and polyamines, but lacks the ability to identify *N*-acetyl-glucosamine and ureides (Warren, 2014b). Finally, pyrolysis in Py–GC–MS can result in secondary reactions, producing artefacts such as aromatic heterocyclic N compounds that may not be present in the original sample (Leinweber et al., 2013). Therefore, the use of multiple coupled separation–MS methods may be required for a comprehensive analysis of organic N compounds (Warren, 2021).

Solid-state ^{15}N nuclear magnetic resonance (NMR) analysis has been used to identify organic N compounds, by identifying and providing the relative abundance for functional groups. This method is non-destructive and independent of the solubility of different organic N molecules. Therefore, it does not require any pre-treatment, minimizing sample disturbance. However, NMR results can be strongly affected by instrumental parameters, as NMR has limited detection capabilities and therefore, it tends to be less sensitive than MS methods (Knicker, 2011). Improvement in this technique may be possible by combining NMR with various separation techniques, including liquid chromatography (LC–NMR). Analysis via a coupled NMR–MS technique can provide identification of organic N compounds with a specificity that may not be possible with either NMR or MS alone.

Other analytical techniques using MS for the characterization of organic N include pyrolysis field ionization MS (Py–FIMS), Fourier-transform ion cyclotron resonance MS (FT–ICR MS), and nanoscale secondary ion MS (NanoSIMS). Py–FIMS combines temperature resolved pyrolysis within an ion source with ionization. Py–FIMS may reduce the secondary synthesis of heterocyclic aromatic N compounds formed from Py–GC–MS by heating the sample stepwise and transferring less energy to the sample, and by application of correction factors that account for pyrolytic formation of artefacts (Leinweber et al., 2013). In FT–ICR–MS, ions are produced by pressure ionization techniques, which are then detected using an oscillating electric field impulse and converted into single frequencies by applying a Fourier transformation. This method is highly sensitive, and capable of high resolution and accuracy. NanoSIMS is a surface analysis technique that provides a wealth of spatially resolved data on a sample, including the molecular, elemental, and isotopic composition (Leinweber et al., 2013). In nanoSIMS, the sample surface is bombarded with a high energy beam comprised of primary ions, which produces secondary ions and ion complexes that can be detected by MS. A drawback of this method is the combination of secondary ion complexes that may interfere with the signal of target species (Leinweber et al., 2013).

Spectroscopic techniques include X-ray photoelectron spectroscopy (XPS) and XANES spectroscopy. In XPS, electrons are excited by focusing energy from an X-ray source onto a sample. Excited electrons can then be used to understand the configuration of N-atoms and individual N-species can be identified and quantified. This methodology requires ultraclean vacuum conditions, as adsorbates from the atmosphere can lead to contamination of the sample. The use of XANES spectroscopy yields electronic and structural information about the compounds of interest, however, XANES regions for identification of compounds overlap significantly, and as such this method is only able to distinguish between general groups of N moieties and thus lacks specificity (Leinweber et al., 2013).

Soil organic nitrogen: An emerging component of soil condition in managed systems

Soil organic N has historically been overlooked as a source of crop nutrition in agricultural systems, which are reliant on inputs of synthetic N fertilizers for their productivity. Consequently, estimated N availability in agroecosystems is often poorly synchronized with crop demand, resulting in economic and environmental consequences (Grandy et al., 2022). As C input in these systems is generally too small to promote microbial immobilization of the excess N fertilizer added, there can be significant leaks via leaching and gaseous N losses (Finney et al., 2015).

Recent developments in agricultural management are centered on the importance of soil condition to improve sustainability and productivity. The soil health concept is an integrative concept linking a diverse set of indicators to the capacity of soil to function as a living ecosystem (Lehmann et al., 2020). However, there is currently a disconnect between C and N in soil health frameworks, and greater integration of organic N cycling within these frameworks will be a step towards improving agroecosystem health (Grandy et al., 2022). A foundational aspect of management decisions guided by the concept of soil health is the recognition that solely managing inorganic N nutrient availability is not sufficient for optimizing plant productivity. As such, recoupling C and N cycles by building up or maintaining organic C and N reservoirs in soil by promoting plant and microbial processes may be a powerful tool to optimize soil N cycling, align soil N supply with plant demand, and minimize environmental losses.

Although the role of organic N in plant nutrition is not fully understood, evidence suggests that agronomically important crops can access a wide array of N sources, which may provide an opportunity to reduce N fertilizer reliance while maintaining or even improving productivity. Improving N use efficiency (NUE), an established metric used to benchmark N management in agricultural systems that has historically ignored the contributions of organic N, may be one means to accomplish this (Congreves et al., 2021). There are several proposed mechanisms by which a greater emphasis on organic N nutrition may improve crop NUE, including: reduced energy costs for the crop, increased root growth, support of healthy soil microbial communities, re-capture of N compounds lost from roots, and matching root uptake capacity to soil N supply (Farzadfar et al., 2021). However, our current understanding of crop organic N uptake and soil bioavailable N uptake is incomplete and closing of knowledge gaps is needed to permit movement toward management strategies that prioritize soil condition, while maintaining crop productivity.

Conclusion

Soil organic N is a term that describes a highly heterogeneous mixture of N-containing organic compounds of various sizes and compositions. Its transformations and cycling are key components of the terrestrial N cycle, including: depolymerization of HMW organic N to LMW organic N, microbial and plant uptake, incorporation into persistent SOM, and leaching of DON to ground and surface waters. Significant advances in analytical techniques and instrumentation in recent years have supported an improved understanding of soil organic N forms and cycling, and future research can build upon this to increase efficiency and mitigate environmental degradation in agroecosystems and other managed systems.

Abstract

Nitrification is the biological conversion of ammonia or ammonium to nitrite or nitrate. Nitrate is mobile in soil and subject to loss by leaching and denitrification. In agricultural soils, loss of nitrate leads to decreased plant available nitrogen and reduces nitrogen use efficiency. Nitrification contributes both directly and indirectly to the production of greenhouse gases, nitrous oxide and nitric oxide. The rate of nitrification in soil is controlled by substrate availability (such as ammonia or urea fertilizers) and environmental parameters of oxygen, water, and temperature. Nitrification can be controlled by limiting substrate availability or with biological or synthetic nitrification inhibitors.

Glossary

Ammonia oxidation First step of nitrification where ammonia is converted to hydroxylamine and then to nitrite.

Anammox Anaerobic ammonium oxidation in which **nitrite** and **ammonium ions** are converted directly into **nitrogen** gas (N₂) and water.

Chemolithoautotrophy A type of microbial metabolism which derives energy from chemical reactions of **reduced** compounds of **mineral** (inorganic or litho) origin, these are used as their electron source. Auto refers to their carbon source which is carbon dioxide or carbonates.

Comammox Complete ammonia oxidation to nitrite and then to nitrate in one organism.

Nitrapyrin Is an organic compound is an organic compound (with the formula ClC₅H₃NCCL₃) used as a **nitrification** inhibitor and bactericide.

Nitrification Is the biological **oxidation** of **ammonia** to **nitrite** followed by the oxidation of the **nitrite** to **nitrate**.

Nitrite oxidation Second step in nitrification where nitrite is converted to nitrate.

Key points

- Nitrification changes the form of nitrogen and increases nitrogen loss from agroecosystems
- Nitrifying microorganisms have unique metabolisms that oxidize nitrogen for energy and use carbon dioxide to grow
- Key enzymes of nitrifiers include ammonia monooxygenase, hydroxylamine oxidoreductase (dehydrogenase) and nitrite oxidoreductase
- Nitrification rates may be controlled by limiting the availability of ammonium and ammonia or by natural or synthetic nitrification inhibitors

Introduction

Nitrification is the biological conversion of reduced nitrogen (N) generally in the form of ammonia or ammonium to oxidized N in the form of nitrite or nitrate. Nitrification converts positively charged ammonium (NH_4^+) into negatively charged nitrite (NO_2^-) or nitrate (NO_3^-), thus changing their interactions with the soil matrix and their availability for plant uptake. The products of nitrification are mobile in the soil and therefore subject to losses from the plant-soil system via leaching and denitrification (see Fig. 1). For these reasons, it is often desirable to manage agricultural soils to reduce nitrification and subsequent N loss, and thereby increase the efficiency of N fertilizers. In animal or municipal waste treatment systems, nitrification is often a desirable process as nitrate is less toxic to aquatic systems than ammonia (NH_3) and can be removed from the waste stream through the denitrification process. The nitrification process is known to produce both directly and indirectly, nitrogenous trace gases, nitric and nitrous oxides important in greenhouse gas and ozone atmospheric chemistry. Since natural and agricultural soils account for a large proportion (>60%) of the total global nitrous oxide production (Tian et al., 2020), managing nitrification and associated downstream processes is important for mitigating the greenhouse effect resulting from terrestrial emissions.

Nitrification processes

The broad definition of nitrification includes a variety of processes by distinct groups of microorganisms that oxidize reduced N to oxidized N, generally in the form of nitrite or nitrate. Nitrification is classically thought of as a process mediated by bacteria that gain energy from the oxidation of inorganic N and fix inorganic carbon (CO_2) and therefore have a chemolithoautotrophic metabolism. The biological nature of this process and the organisms involved were first studied in the late 19th century by Winogradsky (1890-1891) and by Frankland and Frankland (1890). The conversion of N takes place in two phases: in the ammonia oxidizing bacteria such as *Nitrosomonas* or *Nitrospira*, NH_3 or NH_4^+ is converted to NO_2^- . Ammonia oxidizing archaea, such as *Nitrososphaera*, have also been shown to oxidize NH_3 to NO_2^- (Schleper and Nicol, 2010) although by a significantly distinct metabolism from the bacteria. Ammonia oxidizing bacteria and archaea both have ammonia monooxygenase (AMO) enzymes that catalyze the conversion of ammonia to hydroxylamine (Fig. 2). The gene encoding the ammonia monooxygenase subunit-A is often

Fig. 1 Overview of the important role of nitrification in affecting the availability and fate of ammonia/ammonium and nitrite/nitrate for plant uptake or leading to loss of N from the root-zone via leaching or denitrification.

Fig. 2 Outline of nitrification pathway showing some of the important enzymes including: (1) URE: urease is present in some but not all ammonia oxidizing microbes, (2) AMO: ammonia monooxygenase (3) HAO: hydroxylamine oxidoreductase now also known as hydroxylamine dehydrogenase (may not be present in archaeal ammonia oxidizers) (4) NOO: a postulated nitric oxide oxidase and (5) NXR: nitrite oxidoreductase. Only the comammox *Nitrospira* would contain all of these enzymes in a single organism.

used as a molecular marker for ammonia oxidizers. The product of the enzyme hydroxylamine oxidoreductase (HAO) is thought to be nitric oxide (NO), which is then converted to nitrite by an unidentified NO oxidase (NOO) (Lancaster et al., 2018). In archaeal ammonia oxidizers, the similar HAO enzyme is lacking but it is thought that a Cu-enzyme converts hydroxylamine and nitric oxide to nitrite (Lancaster et al., 2018) with NO as a key intermediate. Nevertheless, the net outcome of ammonia oxidation is nitrite as shown in Eq. (1).

In phase 2, nitrite oxidizing bacteria such as *Nitrobacter* or *Nitrospira* convert nitrite to nitrate. This involves the key enzyme nitrite oxidoreductase (NXR) (Fig. 2).

Certain *Nitrospira* bacteria have been found that mediate the entire reaction from ammonium to nitrate within one organism in the Complete Ammonia Oxidation to nitrate known as comammox (Daims et al., 2015; van Kessel et al., 2015).

Other nitrification processes have also been identified as important in specific environments. Heterotrophic nitrification may be broadly defined as the oxidation of reduced N compounds (including organic N) producing nitrite or nitrate. Heterotrophic nitrification is catalyzed by a variety of microorganisms including fungi, and bacteria, including actinomycetes, presumably using a wide variety of metabolic pathways and has been found to be significant in some acidic forest soils. However, the process of heterotrophic nitrification has not been shown to be associated with energy production or to support autotrophic growth of the organisms involved (Stein, 2011).

Anaerobic oxidation of ammonium to dinitrogen gas via hydrazine (Eq. 4) termed the *anammox* process is catalyzed by nitrite dependent anaerobic bacteria belonging to the phylum *Planctomycetes* (Jetten et al., 2009). This process was first found in and is desirable for wastewater treatment systems but also occurs in paddy soils and in oxygen minimum zones of marine systems.

Although the diversity of processes included under a broad definition of nitrification has recently expanded, the aerobic oxidation of ammonia and nitrite by chemolithotrophic bacteria and archaea remains the primary mechanism of nitrification in aerobic agricultural soils.

Trace gas production by nitrification

The main products of nitrification are NO_2^- and NO_3^- which are subject to denitrification reactions that lead to the production of the greenhouse gases nitrous oxide (N_2O) and nitric oxide (NO). In addition to this important but indirect pathway, nitrification processes themselves are known to produce these trace gases as side products and in internal reactions known as nitrifier denitrification. Nitrifiers may produce N_2O by hybrid formation under oxic conditions, namely the abiotic reaction of hydroxylamine, NO, and NO_2^- together or with ferrous iron (Fe^{2+}). Nitrifier denitrification occurs under hypoxic conditions and may release both NO and N_2O . In most aerobic agricultural soils, the amount of direct emission of these trace gases during nitrification is a small proportion of the total emission (Liang and Robertson, 2021; Stein, 2011). However, because NO_2^- and NO_3^- are the substrates for subsequent denitrification, inhibiting nitrification is an effective method for preventing trace gas emissions from agroecosystems.

The organisms of nitrification in soils

The majority of bacteria and archaea that mediate nitrification in soil environments gain metabolic energy from the oxidation of N and use inorganic carbon (i.e. carbon dioxide and bicarbonate) as the primary carbon source for growth of their biomass. This mode of metabolism means that they are highly specialized organisms filling an important role in soil N cycling and N loss. An outline of the process of aerobic chemolithotrophic nitrification showing some of the key enzymes and the groups of organisms involved is shown in Fig. 2. The genes encoding subunits of the key enzymes AMO and NXR are often used as molecular markers for the different groups. The major functional groups of nitrifiers and a representative organism for each from soil if possible is given in Table 1.

In soil environments, the ammonia oxidizing bacteria generally belong to the *Beta-proteobacteria* and include the well-known *Nitrosomonas* and *Nitrospira* genera. Pure culture isolates from soil environments are well-represented in culture collections and by genome sequences (Norton, 2011; Prosser et al., 2014). In most soils, *Nitrospira* outnumber *Nitrosomonas*. The community structure of ammonia oxidizing bacteria is affected by soil agricultural management especially fertilizer application and changing

pH (Prosser, 2011). A meta-analysis of studies quantifying the effect of N fertilizers on the N cycling functional genes found that ammonia oxidizing bacterial abundance increased in response to larger applications and longer duration of N fertilizer use (Ouyang et al., 2018).

The importance of the ammonia oxidizing archaea in soils is indicated by their observed numerical dominance in many systems and their ability to process ammonium in acidic soils. The phylum *Thaumarchaeota* covers the recently discovered diversity of this group of important soil ammonia oxidizing organisms. The groups found in soils are primarily in the order *Nitrososphaerales* and in the *Nitrosotales* order for acid soils (Alves et al., 2018). The diversity and community structure of these organisms are generally determined using the functional gene for the archaeal AMO. A meta-analysis of studies quantifying the effect of N fertilizers on the N cycling functional genes found that ammonia oxidizing archaeal abundance increased in response to larger applications of organic nitrogen amendments at pH >6–8, (Ouyang et al., 2018). This meta-analysis and recent characterization of a soil isolate (Lehtovirta-Morley et al., 2016) suggest that both bacterial and archaeal ammonia oxidizers co-exist and are important in agricultural soils receiving applied nutrients.

Bacteria that oxidize NO_2^- are quite diverse and include members from several phyla including the *Proteobacteria*, *Nitrospirae* and *Nitrospiniae* suggesting that NO_2^- -oxidizing metabolism may have evolved multiple times in evolutionary history. *Nitrobacter* are often isolated from agricultural soils receiving fertilizers, but *Nitrospira* may be numerically dominant. *Nitrospira* also includes the comammox organisms, which as already mentioned, are capable of complete oxidation of ammonium to nitrate. There is convincing metagenomic and isotopic evidence of comammox presence and activity in the soil environment although pure cultures from soil are not currently available. Linking the ecophysiology of the different groups of nitrite oxidizers to their activity and molecular markers remains to be fully realized.

Anammox bacteria are responsible for a significant amount of global N loss from marine, aquatic and terrestrial systems. Their presence and activity are found in various soils mostly in anaerobic or wet environments including permafrost soils, agricultural soils, peat soils and paddy rice soils. The ecological importance of anammox in soil N cycling has not yet been fully explored.

Heterotrophic nitrification may be mediated by a wide range of both bacteria and fungi. Some known heterotrophic nitrifiers including *Paracoccus pantotrophus* are also known aerobic denitrifiers and therefore are of biotechnological and wastewater engineering interest (Duan et al., 2021). While similar bacteria to known heterotrophic nitrifiers are present in most soils their importance to soil nitrification activity remains poorly characterized.

Nitrification in the soil environment and agricultural management

In the majority of aerobic circum-neutral soils, ammonium is rapidly converted to nitrate by nitrification, which increases the mobility of N through the soil matrix, strongly influencing N retention in the system. The factors which control the rate and extent of nitrification and therefore also the populations and community structure of the nitrifying organisms are sometimes typical of general soil microbes but key factors are unique to the nitrifiers. The controlling factors on the rate and extent of nitrification in soils include: substrate supply, environmental conditions, abundance and diversity of nitrifiers, plant and microbial interactions and nitrification inhibitors (Norton and Ouyang, 2019) (see Table 2).

Table 2 Main factors controlling the rates of nitrification in aerobic soils.**Substrate supply**

- 1) Fertilization with ammonia and urea
- 2) Inorganic nitrogen: pools and turnover of ammonium/ammonia, nitrite
- 3) Decomposition - rates of ammonium production via mineralization of organic nitrogen
- 4) Organic nitrogen pools - amounts and characteristics (C/N and complexity)
- 5) Nitrogen deposition to inorganic pools
- 6) Oxygen availability

Environmental soil conditions

- 1) Temperature
- 2) Moisture and Aeration (Oxygen)
- 3) Soil pH

Microbial actors

- 1) Populations of ammonia oxidizers, nitrite oxidizers
- 2) Community structure of ammonia oxidizers, nitrite oxidizers

Nitrification inhibition

- 1) Biological inhibitors produced by plants or other microbes
- 2) Synthetic nitrification or urease inhibitors applied with fertilizers

Adapted from Norton JM and Ouyang Y (2019) Controls and adaptive management of nitrification in agricultural soils. *Frontiers in Microbiology* 10: 1931.

The ammonia oxidizers require NH_3 or NH_4^+ , oxygen and carbon dioxide to proliferate and grow. Since carbon dioxide is always available in soil environments and under well-drained soil conditions oxygen is sufficient for nitrification to proceed, the availability of NH_3 or NH_4^+ limits both the rate of nitrification and the size of the resultant nitrifier population in most agricultural soils. The amounts of substrates available for nitrification include those added as fertilizers, mostly as urea and NH_3 or NH_4^+ in arable soils, urea added by grazing animals, N in wet and dry deposition, and NH_3 or NH_4^+ produced by decomposition of organic N (Table 2). As indicated by Eqs. (1) and (2), both ammonia oxidation and nitrite oxidation require oxygen as a substrate so the aeration status of the soil is a key factor as well.

Both ammonia oxidizing bacteria (including comammox *Nitrospira*) and archaea have AMO enzymes. The substrate for AMO is believed to be NH_3 and is therefore its availability is partially controlled by the pH of the environment. The ammonia: ammonium equilibrium ($\text{pK}_a = 9.25$) means that at pH 6 and lower the availability of free ammonia is very small. Urea is also used directly by some but not all soil ammonia oxidizers as they have a cytoplasmic urease enzyme and have urea transporters. The ability to use urea is an advantage to these organisms especially in acidic soils where ammonia availability is small.

Nitrite does not usually accumulate in soils except under transient conditions that have decreased the population or activity of the NO_2^- -oxidizers. One example is in fertilizer bands of anhydrous ammonia where ammonia toxicity may inhibit nitrite oxidation. When nitrite does accumulate, this often leads to nitric acid that may decompose or be transformed to NO and N_2O gases. The extent of NO_2^- accumulation and subsequent trace gas production is controlled by soil pH, soil buffering capacity, fertilizer formulation and depth of incorporation, and soil moisture (Venterea and Rolston, 2000). A lag effect where ammonia-oxidizers grow and convert ammonia faster than the NO_2^- -oxidizers can respond has been attributed to direct ammonia toxicity or nitrification induced acidity. This effect of the slower growth of nitrite-oxidizers has been counteracted by adding *Nitrobacter* cells to soil slurries (Giguere et al., 2017).

Determination of nitrification rates in soil systems

The term nitrification rate has at least three distinct experimentally defined meanings: *net*, *gross* and *potential* nitrification rates. The net nitrification rate is the rate of accumulation of NO_2^- or NO_3^- and is equal to the rate of NH_3 or NH_4^+ oxidation minus any consumption. This is the most commonly measured rate in both laboratory and field conditions. The gross nitrification rate is the actual rate of conversion of NH_3 or NH_4^+ to NO_2^- and NO_3^- regardless of their consumption by plants, other microbes, and abiotic mechanisms. Determination of gross nitrification rates generally requires the use of isotopes of N specifically the stable isotope ^{15}N . Using modeling and pool-dilution equations investigators determine gross rates of the simultaneous production and consumption of NO_2^- and NO_3^- . The potential nitrification rate is the maximum rate of nitrification in a mixed system with non-limiting substrate (ammonium or ammonia) supply with the elimination of NO_2^- and NO_3^- consumption. Nitrification potentials measure short-term NO_2^- and NO_3^- production in shaken soil slurries with non-limiting substrate supply. These assays are useful indicators of the enzymatic potential for nitrification but are not necessarily predictive of in-situ rates, which are often constrained by substrate availability (Table 2). The details of the methods used for these rate determinations are given in Norton and Stark (2011). Measurements of these different operational rates are often combined to give a clearer view of the nitrification process.

Management of nitrification in agricultural systems

Agriculture is responsible for over half of the input of reactive N to terrestrial systems and improving N availability remains the primary management technique to increase crop yields in most regions. Management actions that decrease nitrification are desirable because they reduce N losses and increase N fertilizer use efficiency. Several approaches are available to control ammonium substrate availability while maintaining crop production. These include nitrogenous fertilizer management based on the '4Rs' approach of applying the right source, at the right rate, at the right time, in the right place (Clarke and Beegle, 2014). Crop rotations and cover and catch crops may be used to decrease ammonium and nitrate pools that are subject to loss. Nitrification inhibitors may be applied with fertilizers to directly control and delay nitrification. Although many appropriate technologies are currently available to reduce nitrification and subsequent greenhouse gas emissions and N losses; these may require appropriate incentives for farmers to adopt. China has some of the most intensive application programs for N fertilizers and the associated high levels of nitrification and nitrate contamination. In a meta-analysis of Chinese agriculture, management practices designed to minimize N loss were assessed including: the application of controlled-release N fertilizers, nitrification and urease inhibitors, higher splitting frequency of fertilizer N application, lower basal N fertilizer proportions, deep placement of N fertilizer, and optimizing N rate based on soil N test (Xia et al., 2017). These knowledge-based N fertilizer application practices were generally effective at reducing N loss by leaching, runoff and greenhouse gas emission and showed some increases in economic return. Split applications of fertilizer-N and the use of enhanced efficiency fertilizers, including those with polymer coatings and urease and nitrification inhibitors, will make increased economic sense if they are used selectively under those environmental conditions where the potential for N loss is high. The goal of nitrification management is to promote a low nitrifying system and reduce N loss and greenhouse gas emissions (Fig. 3).

Fig. 3 Comparison of agricultural management systems resulting in high-nitrifying and low nitrifying agricultural systems. Hypothetic nitrogen pools and flows are represented. Arrows represent nitrogen inputs (green), losses (orange) and transformations (blue). Abbreviations: HMW, high molecular weight; LMW, low molecular weight; DNRA, dissimilatory nitrate reduction to ammonium; ANRA, assimilatory nitrate reduction to ammonium. Nitrification inhibitors

Inhibition of nitrification is an important consideration in three main areas: (1) agricultural N management to increase fertilizer use efficiency and minimize N loss, (2) non-target effects of inhibitory substances in waste treatment systems and in soil ecology, and (3) research investigations of nitrification or nitrifying organisms. The use of synthetic nitrification inhibitors in agriculture is most likely to be economical when nitrate losses are significant, such as in sandy soils, poorly drained soils, or when ammoniacal N is applied in the fall.

Nitrification inhibitors (NIs) slow the microbial conversion of NH_4^+ to NO_3^- , thereby reducing the risk of loss through leaching or denitrification and consequently increasing the N use efficiency of fertilizers. Generally, the first step of nitrification is targeted because accumulation of nitrite is undesirable. Many synthetic nitrification inhibitors act on the AMO enzyme (for example acetylene). Several nitrification inhibitors that are widely used in agriculture include: (1) 2-chloro-6-(trichloromethyl) pyridine (nitrapyrin), (2) dicyandiamide (DCD), and (3) 3,4-dimethylepyrazole phosphate (DMPP). Urease inhibitors, such as N-(n-butyl) thiophosphoric triamide (NBPT), are used to decrease urea hydrolysis and volatilization. Urease and nitrification inhibitors may be used together to delay N movement and slow losses of N. Meta-analyses report that the application of urease and nitrification inhibitors significantly reduced inorganic N leaching (−48%), N_2O emission (−44%), and NO emission (−24%) (Thapa et al., 2016) while increasing crop yield (+7.5%) and N use efficiency (+12.9%) (Abalos et al., 2014). Achieving a beneficial outcome from nitrification inhibitors may depend on the soil environment (e.g. soil pH, texture, temperature) and other management factors (e.g. irrigation and N fertilizer rate). The longevity of the inhibitors under soil conditions as affected by temperature is of key importance for their effectiveness. The effects of several inhibitors on known nitrifiers in pure culture were assessed revealing that nitrapyrin remains one of the best inhibitors of both ammonia oxidizing bacteria and archaea (Papadopolou et al., 2020). The use of synthetic nitrification inhibitors has limitations as they are not allowed in organic production and inhibitors have recently been found off-site in streams (Woodward et al., 2016). In New Zealand, DCD residues were detected in milk resulting in the suspension of DCD use in pastures (Thapa et al., 2016). These observations suggest that organic formulations and biological nitrification inhibitors are desirable alternatives.

Certain plants have been observed to slow nitrification by producing chemicals that act as biological nitrification inhibitors. Inhibitory substances have been isolated from the root systems of tropical pasture grasses that are adapted to low-N environments, in particular the roots of *Brachiaria* spp. have high inhibitory activity. Among field crops, sorghum (*Sorghum bicolor*) root extracts have been observed to inhibit nitrification (Subbarao et al., 2015). Incorporation of these plants into rotations or pasture systems may help to retain N in these soils systems by preventing nitrate accumulations. The search continues for biological nitrification inhibitors for use in the major grain crops especially maize.

Summary and outlook

Nitrification and nitrifying organisms have been studied for well over 100 years yet scientists have recently discovered novel organisms and processes that are involved in soil nitrification around the globe. The diverse nitrifying microbes remain an important example of how management of a microbial process and community may impact agricultural sustainability and the production of greenhouse gases. As we learn more about the ecophysiology of the different groups of microbes responsible for the oxidation of ammonium and ammonia to nitrite and nitrate, we may have the ability to fine-tune the nitrification process in our agroecosystems, improving the use of a vital but limiting soil resource, plant available nitrogen.

Abstract

Denitrification is the transformation of plant available nitrogen (N) to gaseous forms that can return N to the atmospheric pool. Nitrous oxide, N₂O, an important greenhouse gas is formed during both aerobic and anaerobic processes but the concentration of oxygen in the soil determines which processes predominate. The varied nature and uncertainties within the pathways, together with the range of gaseous products makes quantification of losses from soil particularly difficult. Fertilizer N accounts for about 43% of global N₂O releases to the atmosphere from agriculture. The chapter summarizes the fundamental processes of N-transformation that generate gaseous forms of N.

Key points

- Denitrification is the process returning fixed N to the atmospheric pool
- Oxygen depletion triggers denitrification, thereby creating conditions for NO₂[−] and NO₃[−] to be employed as electron acceptors
- Denitrification is carried out mostly by facultative heterotrophic Bacteria, Archaea and, more limited, by certain fungi, often by same organisms that may also carry genes encoding for nitrogenases (N fixers)
- Despite advances in molecular biology, the relationship between gene abundance or enzyme production and denitrification is yet to be consistently quantified
- Abiotic factors still offer the most easily measured inputs for limited modelling of denitrification rates and fluxes

Introduction

Denitrification is the transformation of nitrogen (N) compounds, which are plant available in soil, into gaseous forms, including the climate-forcing N oxides, nitric oxide (NO), nitrogen dioxide (NO₂), nitrous acid (HNO₂) and nitrous oxide (N₂O), and the inert dinitrogen (N₂), that are returned to the atmospheric N-pool. Early research on denitrification was stimulated by the inability

to obtain a mass balance of total inputs and outputs of N in agricultural systems. The large portion of the N left unaccounted was determined to be lost as gaseous N, and which resulted, agronomically, in decreased N fertilizer efficiency.

Research into global change processes identified that one of the gases lost, N_2O , is a potent greenhouse gas with important impacts on our environment. It is currently considered to have a global warming potential over a 100-year that is about 273 times as strong as carbon dioxide, partly due its atmospheric lifetime of about 120 years and because of its significant depletion of the earth's stratospheric ozone layer. As the amounts of industrial or biologically fixed N_2 used for crop production increase, the production of NO and N_2O due to nitrification and denitrification processes will also increase and potentially cause and contribute to a warming of the earth's surface by influencing the radiative budget of the troposphere.

Increasing concern over N_2O as a climate-forcing gas has focused the spotlight on soil use and management for agriculture and forestry, which in combination form the largest source of N_2O emissions in the USA and accounted for 75% of total N_2O emissions in USA during 2021. Rates of N loss from fertilizer applied to agricultural soils through denitrification can vary tremendously, ranging from 0 to 70% of applied N, with mean estimates being about 25%.

The abiotic transformation of N, chemodenitrification, is one mechanism that contributes to total denitrification, especially in some paddy soils and in marine sediments, with nitrate (NO_3^-) and nitrite (NO_2^-) potentially being chemically reduced to N_2O in the presence of Fe^{2+} in an anoxic, neutral to alkaline environment. The soil organic matter (SOM) content is also important, with NO_2^- being preferentially reduced if there is a smaller content but the NO_3^- is preferred at high levels. However, as it is the soil population of microorganisms that plays the dominant role the regulating the N cycle for plant-available N, including the return of N to the atmosphere, the chapter will focus on microbial denitrification.

Definitions and pathways

A number of microbial processes form N_2O and other reduced gaseous forms of N in soil, including nitrification, the oxidation of ammonia, which in water at small concentration is dissociated as the ammonium cation (NH_4^+), to NO_2^- and NO_3^- . The formation of NH_4^+ can be seen as the first step in making N, present in organic form in soil, available as a nutrient to higher plants. However, being a cation, it readily adsorbs to negatively charged surfaces and is therefore of very limited mobility compared with the negatively charged oxides.

Soil organic matter mineralization and inorganic N-fertilizer inputs, now predominantly urea-based ($\text{CO}(\text{NH}_2)_2$), are the main sources of NH_4^+ in the environment. Ammonia oxidation is carried out by several groups of microorganisms through four pathways, including the autotrophic aerobic ammonia oxidization pathway by ammonia-oxidizing bacteria (AOB), archaea (AOA), or complete ammonia oxidization (comammox) bacteria (limited to a few species in the genus *Nitrospira*); heterotrophic aerobic ammonia oxidization (or heterotrophic nitrification) pathway by heterotrophic nitrifying bacteria (HNB, or heterotrophic AOB) and fungi as well as the anaerobic autotrophic ammonia oxidization (anammox) pathway by anaerobic AOB (Table 1).

Substrates, mechanisms and organisms

Aerobic oxidation of ammonia – Nitrification

Nitrification is the oxidation of NH_4^+ or NH_3 via NO_2^- to NO_3^- . Heterotrophic oxidation begins with the oxidation of organic forms of nitrogen to NH_4^+ . Most aerobic oxidation of ammonia in soil is carried out by chemolithoautotrophic members of bacteria (AOB) and archaea (AOA). These organisms first use the enzyme 'ammonia monooxygenase' (amoA) (the polypeptide at the active site of is encoded by the amoA functional gene) to form hydroxylamine (NH_2OH). The archaeal form of amoA has greater affinity for NH_3 than bacterial amoA, which may allow Archaea to be more competitive when substrate concentrations are small, or soil pH is more acid.

In both AOA and AOB the formation of NO_2^- depends on the oxidation of NH_2OH . However, enzyme responsible, 'hydroxylamine oxidoreductase,' only forms NO and to date no enzyme has been identified for oxidizing the NO to NO_2^- . The exact pathway operating in AOA is also still uncertain, possibly following that for AOB or it is possible that NH_2OH reacts with NO to form two molecules of NO_2^- , one of which is reduced to NO and cycles back to react with another NH_2OH molecule. Completion of the oxidation process to form NO_3^- depends on another group of chemolithoautotrophs, the nitrite-oxidizing bacteria (NOB).

Both AOA and AOB release N_2O and HNO_2 following the synthesis of NH_2OH , which is a potentially unstable intermediate in nitrification. Both gases may form without enzyme activity (abiotic), although it is possible that some HNO_2 is produced via an unidentified enzyme. The formation of NO from NH_2OH is the second point where N_2O can be released by AOB together with NO and NO_2 (Fig. 1). In AOA, it appears that it is only NO_2 that is produced at this point. The formation of NO and HNO_2 may also occur following the formation of NO_2^- .

Table 1 Main microbial processes in which reduced nitrogen gasses are formed from organic or mineral forms available to plants.

Microbial process	Main Groups of organisms	Key pathway steps	Reduced gaseous N forms
Nitrification	A. Autotrophic ammonium oxidisers: ammonia-oxidizing archaea (AOA)	AOA: $\text{NH}_4^+ + \text{O}_2 + \text{H}^+ \rightarrow \text{NH}_2\text{OH} + \text{H}_2\text{O}$ $\text{NH}_2\text{OH} + 2\text{H}_2\text{O} + \text{NO} \rightarrow 2\text{NO}_2^- + 7\text{H}^+ +$ $\text{NH}_2\text{OH} + \text{NO} \rightarrow \text{N}_2\text{O} \uparrow + \text{H}_2\text{O} + \text{H}^+$	
	and bacteria (AOB)	AOB: $\text{NH}_4^+ + \text{O}_2 + \text{H}^+ \rightarrow \text{NH}_2\text{OH} + \text{H}_2\text{O} \rightarrow$ $\text{NO}_2^- + 5\text{H}^+$ $2\text{NO} + 2\text{H}^+ \rightarrow \text{N}_2\text{O} + \text{N}_2\text{O} \uparrow + \text{H}_2\text{O}$	N_2O , NO, NO_2 , HNO_2
	B. Heterotrophic ammonium oxidizers (HAOx)	HAOx $\text{Organic-N} \rightarrow \text{NH}_4^+ \rightarrow \text{NO}_2^- \Rightarrow \text{NO}_3^-$	
	C. Nitrite oxidizing bacteria (NOB) D. Comammox	$\text{NO}_2^- + \text{H}_2\text{O} \rightarrow \text{NO}_3^- + 2\text{H}^+ + 2\text{e}^-$ $\text{NH}_4^+ + 2\text{O}_2 \rightarrow \text{NO}_3^- + \text{H}_2\text{O} + 2\text{H}^+$	None N_2O , NO, NO_2 , HNO_2
Nitrifier-denitrification	AOA, AOB, HAOx	$\text{NH}_4^+ \rightarrow \text{NO}_2^- \rightarrow \text{NO} \rightarrow \text{NO} \rightarrow$ $\text{N}_2\text{O} \uparrow \Rightarrow \text{N}_2 \uparrow$	NO, N_2O , N_2
Denitrification	HAOx	$\text{NO}_3^- \rightarrow \text{NO} \rightarrow \text{N}_2\text{O} \text{ or } \text{N}_2$	$\text{NO} \rightarrow \text{N}_2\text{O} \text{ or } \text{N}_2$
Dissimilatory nitrate reduction to ammonia	DNR(A) bacteria and fungi	$\text{NO}_3^- \rightarrow \text{NO}_2^- \rightarrow \text{NH}_4^+$ ↓ $\text{N}_2\text{O} \text{ or } \text{N}_2$	N_2O , N_2
Anaerobic ammonium oxidation	Anammox bacteria	$\text{NH}_4^+ + \text{NO}_2^- \rightarrow \text{N}_2 \uparrow + 2\text{H}_2\text{O}$	N_2O , N_2
N-dependent methane oxidation	Anaerobic methane-oxidizing bacteria	a) Nitrite $3\text{CH}_4 + 8\text{NO}_2^- + 8\text{H}^+ \rightarrow 3\text{CO}_2 + 4\text{N}_2 + 10\text{H}_2\text{O}$ b) Nitrate $5\text{CH}_4 + 8\text{NO}_2^- + 8\text{H}^+ \rightarrow 5\text{CO}_2 + 4\text{N}_2 + 14\text{H}_2\text{O}$	N_2 , N_2O

Organisms that are capable of the complete oxidation of to NH_4^+ to NO_3^- - comammox bacteria – also release N_2O , NO, NO_2 and HNO_2 during aerobic nitrification at the same points as indicted above (Han et al., 2021). Aerobic production of N_2O is considered to be the dominant source of this gas in soils with less than 60% water-filled pore space.

Although the number of archaeal cells carrying out ammonia oxidation is often greater than bacterial cells, the range in yield of N_2O per NO_2^- molecule produced per cell for AOB is from 0.1 to 8%, for AOA it is only 0.04 to 0.3%. AOA are more active than AOB in acidic soils or when concentrations of NH_4^+ are at levels typically associated with organic matter undergoing mineralization. In well-fertilized soils, AOB are more active, being responsible for nearly four times more N_2O production than AOA. The release of NO and HNO_2 is also greater from AOB than AOA or comammox bacteria.

Some nitrifying bacteria that oxidize NH_3 to NO_2^- have some of the denitrifying enzymes that lead to N_2O production. For example, *Nitrosomonas europaea* has a nitrite reductase enzyme and a nitric oxide reductase but no enzyme capable of reducing N_2O . This pathway is known as nitrifying denitrification.

Nitrification has also been found to occur in fungi and heterotrophic bacteria that utilize the same substrate, intermediates and products as autotrophic nitrifiers, and are often able to form N_2O under aerobic conditions. Release of N_2O by heterotrophic nitrification is considered a minor contribution to total N_2O production in soil.

Anaerobic oxidation of ammonia

Formation of N_2O not only occurs during aerobic nitrification but can also be released by autotrophic anaerobic ammonia oxidation (anammox) bacteria. In this case NH_3 is activated by reaction with NO to form hydrazine (N_2H_4), a very powerful reductant. The NO is probably produced by the reduction of NO_2^- by a hydroxylamine oxidoreductase (HAO) reductive homolog HAO_r. This step is the likely source of N_2O , which is one of the gases released in the anammox process. The final step in anammox is the dehydrogenation of N_2H_4 to N_2 gas. The main catabolic enzymes for the process are found in an anammoxosome, a large vacuolar cell organelle with a very dense membrane that prevents the outwards diffusion of the N_2H_4 .

Fig. 1 Pathway and enzymes involved in nitrification.

Anaerobic oxidation of methane

Methanotrophic members of the Archaea and Bacteria use methane as a carbon and energy source. Methanotrophy is an important process in global methane cycling in that it reduces the net methane emission to the atmosphere. Under anoxic conditions in soils and rice paddies, as well as in marine, estuarine and lake conditions, specific methanotrophs have specialized to use different electron acceptors or transferring electrons to syntrophic (sulfate-reducing) bacterial partners. In NO₂⁻ dependent anaerobic methane oxidation (DAMO) metal and metalloid ions, such as Fe³⁺ and Mn⁴⁺, as well as SO₄²⁻, NO₂⁻ and NO₃⁻, are used as electron acceptors and reduced directly. A two-member consortium of a bacteria and an archaeon distantly related to marine methanotrophic Archaea was first identified to carry out DAMO (Raghoebarsing et al., 2006). Eventually, members of the genus *Methyloirabilis*, belonging to the uncultured NC10 phylum, were identified to have DAMO capacity (Guerrero-Cruz et al., 2019). However, while some evidence of *Methyloirabilis* spp. presence in soil has been provided (Bannert et al., 2012), to date its presence is most clearly confirmed for consistently saturated paddy soils, as it is suggested that is a slow grower, sensitive to variability in the redox state and establishes more consistently in more stable anaerobic conditions (Su et al., 2023).

For Nitrite-DAMO, the reaction for methane oxidation is:

And for Nitrate-DAMO:

In both cases, the oxide is reduced to NO and then to N₂ gas and oxygen. The latter is used to oxidize methane mediated by the enzyme methane mono-oxygenase. In a peatland investigation, it appeared that NO₃⁻ acted to inhibit the use of NO₂⁻ as the electron acceptor and was much less effective itself in that role. The known microbes able to carry out this n-Damo process are *Candidatus Methyloirabilis oxyfera* and *Candidatus Methanoperedens nitroreducens*.

Canonical denitrification

Canonical denitrification is defined as the “microbial reduction of nitrate or nitrite coupled to electron transport phosphorylation resulting in gaseous N either as molecular N₂ or as an oxide of N.” The important point being the capture of energy in the high energy phosphate bond in adenosine triphosphate (ATP).

This denitrification process involves a stepwise reduction of N oxides by bacteria or archaea to gaseous products of N₂O or N₂ under limited O₂ conditions (Fig. 2). As indicated above, the process involves the use of NO₂⁻ and NO₃⁻ as terminal electron acceptors instead of molecular O₂ and is irreversible once NO is formed. Thus, a source of organic C is required for microbial metabolism and sufficient NO₃⁻ must be available to act an electron acceptor in an environment with limited O₂. All three conditions, a C source, a low level of O₂ and sufficient NO₃⁻ must be met for denitrification to take place.

Fig. 2 Pathway and enzymes involved in denitrification. Although this Figure was of acceptable resolution, it was also redrafted and resubmitted.

Table 2 Reductases of oxides of nitrogen used in denitrification processes.

Gene markers	Enzyme and function	Organisms
amoA	ammonia monooxygenase subunit A Oxidation of NH_3 to NH_2OH	Autotrophic and heterotrophic Archaea, Bacteria, Fungi.
hao	Hydroxylamine oxidoreductase Oxidation of NH_2OH to NO	Autotrophic and heterotrophic Archaea, Bacteria, Fungi.
hdh	Hydrazine dehydrogenase Oxidation of N_2H_4 to N_2	Anammox bacteria
hzo	Hydrazine oxidoreductase Oxidation of N_2H_4 to N_2	Anammox bacteria
hzs	Hydrazine synthase Reduction of NO to NH_2OH and subsequent condensation with NH_3 to form N_2H_4	Anammox bacteria
nap	Dissimilatory periplasmic nitrate reductase Reduces nitrate to nitrite	Heterotrophic denitrifiers DNRA
nar	Membrane-bound nitrate reductase (narG) Reduction of NO_3^- to NO	Heterotrophic denitrifiers DNRA
nif	Nitrogenase Reduction of N_2 to NH_3	Diazotrophic bacteria and archaea
nir, nirB, nirS, nirK	Nitrite reductases Reduction of NO_2^- to NO by cytoplasmic (nirB), haeme-containing (cd1-S type,) cytochrome or copper-containing (Cu-type, K) enzymes	AOB, AOA, Heterotrophic denitrifiers DNRA organisms Anammox bacteria
nod	Nitric oxide oxidase. Direct oxidation of NO to NO_3^-	Anammox bacteria
nor, cnorB, qnorB	Nitric oxide reductase Reduction of NO to N_2O Cytochrome-containing (cnorB) or quinol-dependent (qnorB)	AOB, Heterotrophic denitrifiers
nos	Nitrous oxide reductase (nosZ, multi-copper) Reduction of N_2O to N_2	Denitrifiers
nrf	dissimilatory periplasmic cytochrome <i>c</i> nitrite reductase Reduction of NO_2^- to NO or NH_3	DNRA
nxr	Nitrite oxidoreductase Oxidation of NO_2^- to NO_3^-	Anammox
$\text{nxr}_{(\text{rev})}$	NO_2^- reduction to HNO_2	

N_2O is produced by the sequential action of NO_3^- , NO_2^- and NO reductases (Table 2), which, however, are generally tolerant of O_2 .

Both the iron-containing cytochrome (S type) nitrite reductase and nitric oxide reductase can catalyze the four-electron reduction of O_2 to water, essential for energy production as ATP in aerobic organisms.

The integrated relationship between the various processes forming the nitrogen cycle is illustrated in Fig. 3.

Genetic insights into microbial diversity, and diversity of genes encoding denitrification enzymes

The advent of Next Generation of Sequencing tools has shown that denitrification genes are widespread in the microbial communities. The stepwise respiratory reduction of NO_3^- to gaseous end products has been shown to involve diverse bacterial taxa of Proteobacteria, Firmicutes, Actinomycetes, Bacteroidetes and Aquificae, and as well as fungi. The polyphyletic origin of denitrification makes it difficult to apply a simple taxonomical approach to describe the primary taxa involved in denitrification. Thus, to understand the diversity of the microbial community involved in respiratory denitrification the diversity of specific denitrification-related bacterial genes is commonly employed. Fig. 2 shows the generic gene markers for the different steps. Reduction of nitrate to nitrite (NO_3^- to NO_2^-), mediated by both denitrifiers and nitrate respirers, involves nitrate reductase encoded by the nar (e.g., respiratory nitrate reductase subunit alpha [narG], respiratory nitrate reductase subunit beta [narH]) and nap (e.g., periplasmic nitrate reductase [napA]) genes. Nitrite reductases encoded by the nir (e.g., Cu-type nitrite reductase [nirK], cytochrome cd1-type nitrite reductase [nirS]) genes are responsible for the reduction of nitrite to nitric oxide (NO_2^- to NO). Reduction to nitrous oxide (N_2O) is catalyzed by nitric oxide reductase, which is encoded by nor (e.g., quinol-oxidizing

Fig. 3 Key steps in the nitrogen cycle and the formation of nitrous oxide, nitric oxide and dinitrogen. Step 1, microbial conversion of dinitrogen gas to ammonia (NH_3) – biological nitrogen fixation by diazotrophic bacteria and archaea– mediated by nitrogenase (*nif*) Step 2, assimilation of NH_3 into amino acids through the glutamine synthetase (*gln*)-glutamate synthase (glutamine 2-oxoglutarate amidotransferase (*glt*) [*GOGAT*]) pathway, which occur in most organisms. Step 3, ammonification of organic matter to release ammonia can proceed with reductive deamination using glutamate dehydrogenase (*gdh*). Step 4, the oxidation of NH_3 to hydroxylamine (NH_2OH) mediated by ammonia monooxygenase (*amo*) in ammonia oxidizing bacteria (AOB), archaea (AOA) and complete ammonia oxidation by Comammox bacteria. Step 5, the oxidation of NH_2OH to nitric oxide mediated by hydroxylamine oxidoreductase (*hao*) in AOB, organisms capable of complete oxidation of ammonia (Comammox) and by hydroxylamine oxidase by some of those capable of anaerobic ammonia oxidation (Anammox). Step 6, the oxidation of NO to nitrite (NO_2^-) by an unknown enzyme. Step 7, the oxidation of NO_2^- to nitrate (NO_3^-) by nitrite oxidoreductase (*nxr*) in nitrite oxidizing bacteria, including Comammox. Step 8, the reduction of NO_3^- to NO_2^- by the same enzyme acting in the reverse. Step 9, the reduction of NO_2^- to NO by nitrite reductase (*nir*) in AOA, AOB, Comammox organisms and heterotrophic denitrifiers. It can also be induced abiotically. Step 10, direct oxidation of NO to NO_3^- mediated by nitric oxide oxidase (*nod*). Step 11, the reduction of NO to N_2O by nitric oxide reductase (*nor*) in AOB, which is a particularly significant source of N_2O . Step 12, the reduction of N_2O to N_2 mediated by nitrous oxide reductase (*nos*) in denitrifier organisms and with Step 13 forms the dissimilatory nitrate reduction to ammonia (DNRA) pathway. Step 13, the reduction of NO_2^- to NH_3 by nitrite reductase (*nrfa*) in DNRA. Step 14, In AOA, there is no known *hao* homolog, so it is hypothesized that NO and NH_2OH react together via a copper enzyme complex to form two molecules of NO_2^- . Step 15, the oxidation of NH_2OH can occur abiotically as well as via cytochrome P460. Step 16, the formation of hydrazine (N_2H_4) from NO and NH_2OH mediated by hydrazine synthetase in Anammox bacteria. Step 17, the formation of N_2 from N_2H_4 mediated by hydrazine dehydrogenase in Anammox bacteria. Step 18, the reduction of NO_2^- to NH_2OH rather than to NO has been found in some Anammox bacteria.

single-subunit class [qnorB], cytochrome *bc*-type complex [cnorB]) genes. The final step, leading to the production of dinitrogen (N_2) is catalyzed by the oxide reductase encoded by the *nosZ* group of genes. The types and amount of the organic carbon can affect microbial activity and thus the proportions of these genes. Some denitrifiers maintain the whole four-gene pathway (*nar*, *nir*, *nor* and *nos*), but others possess partial pathways. It is unclear when ones or the other are favored in a particular environment. Arguably, changes in the ratios of these different genes might inform on the status of the denitrification processes in a soil. Genetic variation in these genes is, however, not easily translated into an extended phenotype for a population of denitrifiers. Furthermore, the sensitivity to environmental conditions of genes encoding equivalent functions may vary; for e.g., *nirS*-type denitrifiers was reported to be more sensitive to the soil type, soil moisture, pH, and rhizosphere effect than *nirK*. Such variability suggests both that denitrification can be affected by changes in the environment, and also that redundancies in encoding genes make it resilient to same changes. Generally, the rates of the transient production of NO_2^- , NO and N_2O that occurs during transition from oxic to anoxic respiration are better related to the abiotic conditions and seem not to be dependent on the taxonomy of the communities of denitrifiers.

Denitrification under field conditions

Measurements of loss of gaseous forms of N from soil under field conditions have large coefficient of variation, which has been attributed to the formation of soil “hotspots” that exhibit increased soil respiration. Spatial variability in N_2O fluxes typically causes coefficients of variation from 30 to 100% to be measured at a spatial scale of several meters with field plots. Hotspots of organic debris can stimulate denitrification due to rapid microbial mineralization and release of NH_4^+ leading to NO_3^- with concomitant depletion of O_2 concentrations. The best field indicator for denitrification has been found to be drainage class, which determines the potential for the soil to become waterlogged at times of intense precipitation. Seasonal differences in frequently noted for denitrification events (less in spring vs. more in fall) have been attributed to smaller concentrations of NO_3^- in spring in temperate soils. Larger inputs of organic material close to the soil surface supports greater microbial activity and can result in increased

denitrification compared with that in deeper layers with less C available. Furthermore, 30–80% of the N_2O produced at deeper soil layers can be reduced to N_2 before exiting the soil (Clough et al., 2005).

The genera of denitrifying bacteria are diverse. The capacity for denitrification has been reported to be present in more than 50 genera of bacteria. Although the distribution of denitrifiers is ubiquitous, the activity or measurement of denitrifier biomass and synthesis of denitrifying enzyme activity from soil field cores is poorly correlated with measured N gas loss. Yeast and filamentous fungi are also capable of gaseous N production. Fungal N_2O production may be of great significance because fungi often dominate the microbial biomass of temperate soils, yet fungi are not tolerant of waterlogged conditions. Denitrifiers are not fermentative (facultative anaerobes), hence their growth under oxygen-limited conditions is solely dependent on the presence of N oxides. In this process, N_2O is an intermediate and so the ratio of $\text{N}_2\text{O}:\text{N}_2$ fluxes can be affected by various environmental factors. The proportion of N_2O compared to N_2 is increased if the soil pH is decreased, if the amount of NO_3^- is increased, and if smaller O_2 concentrations are present. In each case, the environmental factors have an influence on the enzyme nitrous oxide reductase.

A clear distinction between this canonical denitrification pathway and other denitrification pathways is necessary as the relative proportion of N_2O production from the various mechanisms is affected by the environmental conditions that prevail. The denitrification pathway is prevalent once NO_3^- is formed and the correct environmental conditions of O_2 concentrations, and soluble C are present with microbial reduction of the N oxides resulting.

Heterotrophic denitrification to N_2O

Production of N_2O and NO following the reduction of NO_3^- or NO_2^- to NH_3 increases as the O_2 concentration decreases from fully oxygenated (21%). Under hypoxic conditions, between 3 and 0.5%, the contribution to total N_2O production by heterotrophic denitrification can be as much as 50% and can account for all N_2O production under anoxia. The fungus *Aspergillus flavus*, a model organism for heterotrophic nitrification, especially in relation to acidic forest soils, produces NO_3^- for denitrification by oxidation of amino acids, such as aspartate, when its preferred carbon and energy source has been depleted.

Nitrifier denitrification

When O_2 concentrations become insufficient to support NO_2^- oxidation to NO_3^- by NOB, ammonium oxidizers can produce N_2O from NO_2^- in a process known as nitrifier denitrification. This reaction, first identified in AOB, differs from that of canonical denitrifiers because it is not coupled with the oxidation of organic C. The pathway operates under aerobic oxidation of NH_3 but at a slower rate than in micro-aerobic conditions. First, the enzyme nitrite reductase (nir) reduces NO_2^- to NO, which is reduced in turn to N_2O via nitric oxide reductase. It is important to recognize that this production of N_2O does not need anoxic conditions. A portion may be further reduced to N_2 gas.

The relative proportion of nitrifier denitrification to the N_2O budget ranges from 0 to 30% of the total N_2O released. Use of molecular probes specific for genes encoding for heme-type dissimilatory nitrite and nitrous oxide reductase gene homologies derived from *N. europaea* gene sequences has found that prominent nitrifiers of the genera *Nitrosospira* and *Nitrosolobus* may differ from *N. europaea* in the mechanism and capacity for denitrification.

Dissimilatory nitrate reduction to ammonia or nitrate ammonification

Chemoorganoheterotrophic bacteria, methane-oxidizing archaea, and fungi can carry out dissimilatory nitrate denitrification to ammonia (DNRA) in which NO_3^- is first reduced to NO_2^- , replacing O_2 as the electron acceptor in a respiratory electron transport chain. The associated oxidative phosphorylation provides energy in the form of ATP. The further reduction of NO_2^- to NO_3^- can take place, either in the same respiratory process (the respiratory pathway) or using energy from phosphorylation of a carbon substrate (fermentation pathway). Reduction of NO_3^- to NO_2^- is mediated by a periplasmic nitrate reductase encoded by narG. Reduction of NO_2^- in the fermentation pathway involves nitrite reductase enzymes coded by nirB, whereas the enzyme involved in the respiratory pathway is encoded by nrfA. The latter is found in bacteria capable of DNRA from different phyla (e.g., Bacteroides, Firmicutes, Planctomycetes and Proteobacteria) and can be used as a molecular marker for this pathway, with positive associations between gene abundance and DNRA activity (Pandey et al., 2020).

Although the reduction to NH_4^+ can account for over 90% of the NO_3^- entering the DNRA pathway, ^{13}N -labelling has shown that there is some N_2O produced in the process. Under conditions with greater carbon input elevated C:N ratio, production of NH_4^+ by DNRA is enhanced relative to the products of denitrification. In contrast, high levels of nitrate, small C:N ratio, favor denitrification over DNRA.

Environmental factors

Denitrification supports microbial life through respiration as mineralization of a reduced substrate (mainly organic C, but reduced iron or sulfur may also donate electrons) donates electrons via carriers to an oxidized N oxide. The decline in free energy is coupled

with the generation of ATP. In the presence of O_2 , the ATP yield per number of electrons transported is about 1.7 times greater than if NO_3^- is the terminal electron acceptor, with the final efficiency apparently being species dependent.

Organic C availability

The availability of a suitable reduced C source is important because of the strong relationship between denitrification and soil organic matter. More important, the water-soluble portion of the soil organic matter has been found to be a good indicator for potential denitrification. Recent work has also found that organic litter with low C:N ratios has a greater potential to promote higher denitrification activity than litter with higher C:N ratios. Animal manures with a readily decomposable C source and a high N content can greatly enhance soil denitrification rates.

The presence or absence of plants has also been found to affect denitrification rates. Higher denitrification rates have been noted in the plant rhizosphere as compared with bulk soil several millimeters away from the roots if NO_3^- was sufficient, but if NO_3^- availability was limited, the presence of plants decreased denitrification activity. Plant roots have the potential to impact denitrification activity by providing C to support microbial populations and supply electrons for NO_3^- reduction. Roots can also create anaerobic zones through respiratory O_2 consumption when O_2 supply is limited by water conditions. The rooting environment can create a drier soil through evapotranspiration processes and result in increasing O_2 diffusion in the drier soil. Roots can also assimilate NH_4^+ and NO_3^- from the soil solution reducing the availability of substrate to the denitrification pathways.

Due to a typical decrease in available soil C with depth, denitrification activity has also been found to decrease with soil depth and is potentially limited by a lack of available C below 60 to 75 cm. Other soil characteristics can also change with depth concomitant with organic C content such as porosity/permeability, pH, temperature and depth to water table that may also have an impact in denitrification rates.

Controls on O_2 availability

Reduced availability or absence of O_2 is required for both the synthesis and activity of enzymes involved in denitrification. Soil parameters can control overall O_2 availability and influence denitrification rates. The universally recognized inverse relationship between water content and denitrification is due to the slower the diffusion of O_2 to metabolically active sites with greater the amounts of water present in the soil matrix. Bulk soil parameters that have been used to describe O_2 control of denitrification include soil moisture content, soil water potentials, partial pressure of O_2 , O_2 concentration in solution, percentage air-filled porosities and redox potentials. Bulk measurements have shown promise for predicting denitrification activity in laboratory studies, but in field measurements, spatial variability due to hot spots can mask the predictive nature O_2 diffusion or C mineralization rates.

Soil texture is an important factor for determining critical air-filled porosity, as a finer textured soil (less sand content) will have a higher critical air-filled porosity value than found for coarser textured soils. Oxygen concentrations in soil atmospheres at which denitrification has been observed for different soil types ranged from 4% to 17%. Although the bulk soil O_2 concentrations are important, it has been noted that the O_2 concentration at the microsite level are more important for determination of denitrification activity.

The occurrence of anaerobic microsites can explain how an O_2 sensitive process is possible in a well-structured soil having bulk O_2 measurements indicating aerobic conditions. The microsite concept proposes that anaerobic sites occur within centers of water saturated soil aggregates because of limited diffusion of O_2 and consumption of O_2 by microbial metabolism. Research has shown that the occurrence of anaerobic microsites is largely a function of localized C availability and is possible within aggregates exceeding 9 mm. The microsites are more likely to occur in the rhizosphere and with particles decomposing plant litter in zones where water can limit O_2 diffusion. Again, denitrification activity is a function of available C, limited O_2 potentials and a source of N oxides.

Nitrate supply

Research has indicated that the rate of denitrification activity in pure culture studies was independent of NO_3^- concentration. Recent research has reported first order kinetics with NO_3^- concentrations below 40 mg l^{-1} and the kinetics changed from first order to zero order for NO_3^- concentrations above 100 mg. Microbial NO_3^- reduction is an enzyme catalyzed reaction and use of Michaelis-Menten kinetics has found K_m values for NO_3^- reduction to be <15 μM NO_3^- or about 93 μg NO_3^- l^{-1} for several bacterial isolates. The use of K_m values determined that concentrations required for NO_3^- reduction are higher for soils than those found for pure culture or enzyme studies. The rate kinetics also change if the soil has recently received chemical fertilizers. However, Michaelis-Menten kinetics has not been found to accurately describe NO_3^- reduction dependence on available C and NO_3^- concentrations in soil. Several studies have found that kinetic analysis may not reflect denitrification rates, but the rate of NO_3^- diffusion from solution into the actively denitrifying soil aggregate. The evidence indicates that even very low NO_3^- concentrations present in soil solutions are in excess of enzyme and microbial needs for terminal electron acceptors during O_2 stress, but denitrifying activity may actually be limited by the diffusion of NO_3^- into the soil microsites.

Temperature

Denitrification, because of enzyme dependence on temperature for the activity rate, would be expected to increase exponentially with increased temperature within the range of enzyme activity. The temperature effect is impacted by the interaction of temperature on O_2 solubility and O_2 consumption as well as O_2 diffusion. Decreasing temperature will increase O_2 solubility and decrease O_2 consumption. Research has found a minimum soil temperature range of 2.7–10 °C for denitrifying activity and a maximum temperature of about 50 °C. Above 50 °C, chemical decomposition reactions of NO_2^- can complicate the denitrification-temperature relationship. Pure culture experiments with soil isolates found 30 °C to be the optimum temperature for growth, but evidence suggests that denitrifiers are adapted to soils and growth conditions of the specific soil. Bacterial isolates from tropical soils (33 total) showed no growth when incubated at 10 °C whereas 68% of temperate soil isolates (95 total) grew at 10 °C.

pH

The pH requirement for denitrifying organisms appears to be similar to heterotrophic organisms. In the neutral pH range from 6 to 8, there is a limited effect of pH on the activity of denitrification, but denitrification rates can be limited in acid pH ranges. Adjusting a naturally acid soil (pH 3.5) with reduced microbial activity to pH 6.5 rapidly stimulated a strongly increase in denitrification rates and suggests that a general population with neutral growth optimum was present in a low pH environment. Research has suggested that the decrease in denitrification activity in a moderately acid environment favors NO_3^- reduction to NH_4^+ and that increased soil acidity may favor NO_3^- reduction rather than denitrification. Isotopic evidence has suggested that although moderate change in pH (pH 6.7 to 5.2) had little effect on the total rate of N_2 and N_2O production, the pH adjustment resulted in a rapid change from predominately N_2 production at pH 6.7 to predominately N_2O at pH 5.2. Due to the ratio change noted with change in soil pH value, the enzyme N_2O reductase may be extremely sensitive pH.

Conclusion

Several microbiological mechanisms occurring in soils can give rise to gaseous loss of N. Denitrification and nitrifier denitrification are biological pathways that are very closely linked by the production of NO_3^- in soils and sediments. The requirements for denitrification activity include a reduced C source, a NO_3^- pool and an O_2 limited environment. Under anoxic conditions, many facultative heterotrophic microbes carry out denitrification and reduce NO_3^- to NO_2^- , which is then reduced to N_2O and, in microaerobic or anaerobic conditions, to N_2 (coupled nitrification–denitrification). The $N_2O:N_2$ ratio produced by the denitrification pathway can be increased by increased NO_2^- and NO_3^- concentration. The ratio can also be increased by decreased O_2 concentration, pH values and increasing the C availability. The spatial variation of soil C and N and low O_2 tensions required for denitrification during field quantification and the importance of nitrifier denitrification processes are crucial areas of research that need to be understood before management of gaseous N loss can be achieved.

Abstract

Nitrogen is an essential nutrient in plant growth. The ability of a plant to supply its requirements from biological nitrogen fixation through interactions with associative, endophytic and endosymbiotic symbionts, is of tremendous importance to the environment and world agriculture. Symbiotic nitrogen fixation is part of a mutualistic relationship, in which plants provide a niche and fixed carbon to bacteria in exchange for fixed nitrogen, and relies on complex regulatory circuits between both partners. This process is restricted mainly to legumes in agricultural systems, and there is considerable interest in exploring whether similar symbioses can be developed in non-legumes.

Key points

- Availability of nitrogen (N) is one of the principal elements limiting growth and development of crops.
- Biological nitrogen fixation is the ability of diazotrophic bacteria to reduce atmospheric N₂ to NH₃, which is readily assimilated into biological molecules.
- Most legumes and a few non-legumes form intimate, nitrogen-fixing symbioses with diazotrophs that provide the plants with ammonia.
- Many important food species cannot establish effective nitrogen-fixing symbioses with diazotrophs.
- Large-scale use of industrially-produced N-fertilizer has doubled the influx of N into the terrestrial biogeochemical N-cycle; therefore, the long-term sustainability of massive N-fertilizer inputs in agriculture has come into question.
- The threat to sustainability has created a strong driver to provide an alternative to synthetic nitrogen by engineering biological nitrogen fixation in plants.

Introduction

In agroecosystems, nitrogen is one of the major nutrients limiting plant growth. To meet the increased nitrogen demand in agriculture, synthetic fertilizers have been used extensively which have led to environmental challenges such as nitrate pollution. Biological nitrogen fixation is the conversion of atmospheric nitrogen (N_2) to ammonia (NH_3), a form that can be used by plants. However, the process is restricted to bacteria and archaea and does not occur in eukaryotes. The bacteria responsible for nitrogen fixation are called diazotrophs; they encode nitrogenase, the oxygen-sensitive enzyme complex that catalyzes the conversion of N_2 to NH_3 . Diazotrophs are found in several phyla and representatives from most (if not all) of these phyla are known to engage in nitrogen-fixing symbiosis with plants. Symbiotic nitrogen fixation is part of a mutualistic relationship in which plants provide a niche and fixed carbon to bacteria in exchange for fixed nitrogen. Depending on environmental conditions, symbiotic nitrogen fixation may be tuned to the plant's nitrogen demand or specifically inhibited, or even prevented. Therefore, diazotrophs have evolved elegant strategies to tightly regulate the expression and activity of components required for biological nitrogen fixation. Biological nitrogen fixation by legumes, and by associative, endophytic, and endosymbiotic nitrogen fixation in non-legumes play major roles in reducing the use of synthetic nitrogen fertilizer in agriculture, increased plant nutrient content, and improving soil fertility. However, symbiotic nitrogen fixation, largely restricted to legumes, is not directly available to the most agriculturally important crops. It has thus been a focus to develop different strategies to transfer the ability to fix nitrogen to cereals.

Biological nitrogen fixation and nitrogenase enzymes

Biological nitrogen fixation refers to the enzyme-catalyzed reduction of N_2 to NH_3 , and occurs exclusively in microorganisms called diazotrophs. Diazotrophic activity accounts for approximately two-thirds of the fixed N available to the biosphere (Rubio and Ludden, 2008) and diazotrophs are distributed across multiple phyla of Bacteria and Archaea (Boyd et al., 2011). Diazotrophs represent ~7.8% of all bacterial and archaeal cultivars with sequenced genomes and are characterized by organisms operating aerobic, anaerobic, phototrophic, chemotrophic, autotrophic, and heterotrophic metabolisms. Known bacterial diazotrophs were found in 13 taxonomic phyla: Actinobacteria, Aquificae, Chlorobi, Chloroflexi, Chrysiogenetes, Cyanobacteria, Deferribacteres, Firmicutes, Fusobacteria, Nitrospirae, Proteobacteria, Spirochaetes, and Verrucomicrobia. Unlike bacterial species, nitrogen fixation in Archaea is contained only within the phylum Euryarchaeota. Diazotrophs are found in a wide variety of states and habitats including free-living in soils and water, associative symbioses with grasses, symbiotic actinorhizal associations with woody plants, cyanobacterial symbioses with various plants and root-nodule symbioses with legumes (Dos Santos et al., 2012).

Biological nitrogen fixation is catalyzed by the enzyme complex nitrogenase. The nitrogenase enzyme occurs in three different isoforms: Mo-nitrogenase, V-nitrogenase, and Fe-only nitrogenase. The Mo-nitrogenase (Nif) is found in all diazotrophs and is the only nitrogenase known in diazotrophs forming symbioses with higher plants. The two alternative nitrogenases, the V-nitrogenase (Vnf) and the Fe-only nitrogenase (Anf), are found in free-living soil bacteria, archaea, and cyanobacteria. Biological nitrogen fixation is usually considered to rely primarily on the more efficient canonical Mo-nitrogenase, whereas the V-nitrogenase and the Fe-only nitrogenase are often considered "backup enzymes", used when Mo is limiting. Indeed, nitrogen-fixing symbionts with higher plants such as *Rhizobium* and *Frankia* do not possess alternative nitrogenase genes and are believed to be the major contributors to biological nitrogen fixation. If the environmental distribution and diversity of alternative nitrogenases remains largely unknown, numerous lines of evidence suggest that alternative nitrogenases are significant contributors to biological nitrogen fixation in terrestrial ecosystems and can contribute up to 70% of the total biological nitrogen fixation in some diazotrophs (e.g., cyanolichens).

Despite differences in their metal content, the three nitrogenase enzymes are structurally, mechanistically, and phylogenetically related. The most intensively characterized system is the canonical Mo-nitrogenase, a complex two component metalloenzyme comprised of two proteins. The smaller dimeric component, known as the iron protein or dinitrogenase reductase (NifH protein), functions as an ATP-dependent electron donor to the larger heterotetrameric component, known as the molybdenum-iron protein or dinitrogenase (comprising the NifD and NifK component proteins), which contains the enzyme catalytic site (Fig. 1) (Seefeldt et al., 2009). Both nitrogenase-component proteins are extremely oxygen sensitive. The two other nitrogenases, V- and Fe-only nitrogenases, are enzyme homologs, except for an additional subunit (VnfG or AnfG) in the dinitrogenase component, and the absence of the heteroatom Mo. The three nitrogenases differ greatly in their catalytic activities: the Mo-nitrogenase requires 16 mol of ATP per mole of N_2 (Fig. 1), versus 24 and 40 mol of ATP per mole of N_2 for the V- and Fe-only nitrogenases, respectively, as assessed with in vitro assays (Mus et al., 2018).

The Mo-, V-, and Fe-only nitrogenases are genetically distinct as they are encoded by separate gene clusters designated, *nif*, *vnf*, and *anf*, respectively. The structural components of the Mo-nitrogenase are encoded by *nifH*, *nifD*, and *nifK* genes. The V-nitrogenase is encoded by *vnfH*, *vnfD*, *vnfG*, and *vnfK*, and the Fe-only nitrogenase components are products of *anfH*, *anfD*, *anfG*, and *anfK* genes. Apart from the catalytic components, additional gene products are required to produce fully functional nitrogenase enzymes. Although the number of proteins involved in the activation of nitrogenases seems to be species-specific and varies according to the physiology of the organism and environmental niche. Extensive biochemical and genetic characterization has implicated at least 82 genes products in the formation and regulation of the three forms of nitrogenases. Global transcriptional profiling studies of nitrogen-fixation reported in different diazotrophic bacteria were valuable for defining the full extent of the *nif*, *vnf*, and *anf* gene clusters and for identifying genes that are coordinately expressed with particular nitrogenase but not directly involved in nitrogen

Fig. 1 Structure and stoichiometry of the Mo-nitrogenase enzyme. (a) Structure of the *Azotobacter vinelandii* Mo-nitrogenase enzyme complex (NifHDK; PDB 1M34; Schmid et al., 2002) showing the MoFe (NifD, in grey; NifK in blue) and Fe protein (NifH, in pink) components. The active-site FeMo-cofactor of Mo-nitrogenase is circled. (b) Stoichiometry for N_2 reduction catalyzed by the Mo-nitrogenase enzyme.

fixation (non-specific nitrogen-fixation genes involved in different functions such as transport and secretion, iron-sulfur cluster assembly system, respiratory and energy metabolism, electron transport, nitrogen and carbon metabolism, secondary metabolism, translation and transcription) (Mus et al., 2018).

Diversity of nitrogen-fixing plant-microbe associations

Various types of associations/interactions occur between diazotrophs and their host plants including associative interactions, endophytic associations, and endosymbiotic associations (legume and non-legume symbioses) (Fig. 2). In all these associations and symbioses, for the host plants the expected benefit of the interaction is the fixed nitrogen provided by the symbiotic partner,

Fig. 2 Nitrogen-fixing plant-microbe interactions or associations exhibit different degrees of intimacy: associative interactions, endophytic associations, and endosymbiotic associations. Free-living and associative diazotrophs (e.g., *Azospirillum*, *Azotobacter*, *Nostoc*) may be enriched within the rhizosphere and benefit directly from plant root exudates. The plant may benefit from released nitrogen, but has little control over the exchange. Endophytic diazotrophs spread and multiply within plant tissues without causing damage and eliciting significant defense reactions as they do not reside intracellularly in living-plant cells. Endosymbiotic diazotrophs (e.g., *Azoarcus*, *Herbaspirillum*, *Gluconacetobacter*, *Nostoc*) colonize different plant organs intracellularly. Endosymbiotic diazotrophs (e.g., *Rhizobia*, *Frankia*) accommodated inside plant cells within plant-derived membranes known as nodules. The plant has a high degree of control and symbiosis is very specific.

which, in return, receives reduced carbon and possibly all the other nutrients it requires. In addition, the symbiotic or endophytic plant structure colonized by the nitrogen-fixing microorganisms may provide the appropriate conditions for protecting the nitrogenase complex from oxygen exposure.

Associative nitrogen-fixing interaction

Bacteria that colonize the rhizosphere are called rhizobacteria, and rhizobacteria with beneficial effects on plant development are referred to as plant-growth-promoting rhizobacteria (PGPR). Some of these PGPR are diazotrophic bacteria and have the ability to develop root associations with different plants including grasses. Interactions between plants and associative nitrogen-fixing bacteria are the simplest form of nitrogen-fixing symbiosis (Fig. 2) (Mus et al., 2016). Diazotrophic rhizobacteria have been identified in several genera of alpha- and β -Proteobacteria including *Acetobacter*, *Azoarcus*, *Azospirillum*, *Azotobacter*, *Burkholderia*, *Enterobacter*, *Herbaspirillum*, *Gluconobacter* and *Pseudomonas*. These associative diazotrophic nitrogen-fixing bacteria respond to root exudates via chemotaxis to, and colonization of, the rhizosphere of many plants but do not invade plant tissues. Many of these bacteria can live in association with maize, rice and wheat, and to contribute to improved plant growth (Santi et al., 2013).

Endophytic nitrogen-fixing associations

Many species of diazotrophic bacteria have evolved beyond surface colonization to spread and multiply within plant tissues without causing damage and eliciting significant defense reactions, they are usually designated endophytic nitrogen-fixing bacteria (Fig. 2). Endophytic bacteria invade plant tissues, but they differ from endosymbionts, as they do not reside intracellularly in living plant cells and their colonization does not induce the formation of any differentiated plant structure. Endophytes are ubiquitous, likely form colonies in all plants, and have been isolated from almost all plants examined to date. Their association can be obligate or facultative and causes no harm to the host plants. They exhibit complex interactions with their hosts which involves mutualism and antagonism. *Azoarcus* spp., *Herbaspirillum seropedicae* and *Gluconobacter* are recognized as endophytes. They differ from other rhizobacteria such as *Azospirillum* and *Azotobacter*, in that 'they are tightly associated with plants and do not survive well in soil' (Santi et al., 2013). Cyanobacteria are also frequently found within plant tissues. *Nostoc* is endophytic with two genera of liverworts (*Blasia* and *Cavicularia*) and all hornworts. Colonization can take place in dome-shaped auricles on the thallus of liverworts or in slime cavities of the thallus or mucilage-filled canals that run parallel to the thallus of hornworts. *Nostoc* is also able to endophytically colonize coralloid roots of cycads. The mechanism of recruitment is unknown, but the cyanobacteria are found embedded in mucilage in a specific cortical layer of the coralloid root between elongated specialized cells.

Endosymbiotic nitrogen-fixing associations

The highly specific and most efficient processes for nitrogen fixation involve the formation of root nodules on legumes and non-legumes (Fig. 2). The diazotrophic bacteria involved in these endosymbiotic interactions include *Rhizobia* (Gram negative) members of the alpha-subgroup of the phylum Proteobacteria that associate with legumes (family Fabaceae) and the non-legume *Parasponia* species (family Cannabaceae); *Frankia* sp. (Gram positive) members of the actinomycete family that associate with a broad spectrum of plants belonging to eight families collectively called actinorhizal plants; and nitrogen-fixing cyanobacteria (mainly *Nostoc* sp.) that have also been found to colonize different plant organs intracellularly in the family Gunneraceae (Santi et al., 2013).

Rhizobium-legume symbiosis

The nitrogen-fixing symbiosis is predominant in leguminous plants belonging to the family Fabaceae. Legume-*Rhizobium* symbiosis starts with a molecular dialogue between the two partners. The legume secretes a cocktail of phenolic molecules (flavonoids and isoflavonoids) into the rhizosphere. These signals are taken up by rhizobia, bind the transcriptional regulator NodD, and activate a suite of bacterial nodulation genes. These nodulation genes are responsible for the production of lipochitooligosaccharides (LCOs) called Nod factors which are indispensable in the specific host-*Rhizobium* interaction and at later stages in the infection process and nodule organogenesis. In the initial stages of infection, rhizobia attach to the root hair surface in a process that may involve a number of different mechanisms, mediated by means of adhesion proteins on the bacterial cell surface that recognize specific determinants of the plant cell wall. Invasion of the plant starts with an infection-thread, through which bacteria enter the root hair and move, at a high rate of proliferation, towards the root cortex, where they differentiate into nitrogen-fixing bacteroids within a unique plant organelle called the symbiosome. The symbiosome is delimited by a plant-derived membrane that controls nutrient exchange between the symbionts. Two main types of nodules are formed on the various legume species, indeterminate (apical meristem and developmental gradient) or determinate (no apical meristem and no developmental gradient), depending on whether or not the meristem remains active for the life of the nodule, respectively. The symbiosomes of determinate nodules usually contain a small number of bacteroids that are of a similar shape and size as free-living bacteria, while symbiosomes from indeterminate nodules usually contain a single swollen and pleomorphic bacteroid. Both of types of legume nodules have a peripheral vasculature, in contrast to roots (Rashid et al., 2015).

Actinorhizal symbiosis

Actinorhizal plants have the ability to develop an endosymbiosis with the nitrogen-fixing soil actinomycete *Frankia*. *Frankia* is a genus of soil actinomycetes in the family Frankiaceae that fix nitrogen, both under symbiotic and free-living aerobic conditions, while most rhizobia do not. Over 200 strains of *Frankia* have been isolated from many actinorhizal plant species in the plant

families *Betulaceae*, *Casuarinaceae*, *Coriariaceae*, *Datisceae*, *Eleagnaceae*, *Myricaceae*, *Rhamnaceae*, and *Rosaceae*. In both the free-living and the symbiotic state, nitrogen fixation takes place within the swollen tips of hyphae termed vesicles that are encased in multilayered hopanoid-rich membrane envelopes that provide the necessary O₂ protection to prevent nitrogenase inactivation. The strategies used by *Frankia* spp. to infect actinorhizal plants are quite similar to those used by rhizobia. The establishment of the symbiotic process results in the formation of root nodules in which *Frankia* provides fixed nitrogen to the host plant in exchange for reduced carbon. Depending on both the host species and *Frankia* clade, infection can either take place via infection threads or by crack entry. Unlike legume root nodules, the root nodules of these non-legumes are modified lateral roots with a central vascular system and a peripheral infected expanded cortex (Santi et al., 2013; Rashid et al., 2015).

Parasponia-rhizobium symbiosis

In the order Rosales, in addition to actinorhizal nitrogen-fixing plants, *Parasponia* species (family Cannabaceae) also display an original nitrogen-fixing root symbiosis. *Parasponia* is the only non-legume host plant known to be nodulated by rhizobia. Like in most legume-*Rhizobium* symbioses, the *Parasponia*-rhizobium symbiosis depends on Nod factors. The infection process that leads to nodule development occurs via the so-called crack entry mode of infection. The rhizobia remain in threads throughout the symbiotic process and are not released from the threads, unlike the process of bacteroid formation in legume-*Rhizobium* symbioses. The final structure of the *Parasponia* nodule lobe is similar to that observed in actinorhizal symbiosis and resembles lateral roots (Santi et al., 2013; Rashid et al., 2015).

Cyanobacterial endophytic and endosymbiotic associations

The intimacy of the symbiosis *Gunnera-Nostoc* is therefore greater than in other cyanobacterial associations since the cyanobacteria are hosted intracellularly, whereas in bryophytes, *Azolla* and cycads, the cyanobionts occur as endophytes in mucus-filled cavities. The cyanobiont *Nostoc* enters *Gunnera* plants through specialized glands located on the stem. The glands secrete polysaccharide-rich mucilage that attracts specific symbiotic cyanobacteria, supports their growth on the gland surface, and contributes to their differentiation. After entering the gland through existing channels, cyanobacteria induce divisions in the host cells lining the channel and are subsequently taken up into the host cells. The conversion of vegetative filaments into motile and short-lived hormogonia is an essential step for the establishment of the symbiotic process. Different environmental stimuli and plant factors released during nitrogen starvation can stimulate the induction of gliding filaments known as hormogonia. Hormogonia play a major role in short-distance dispersal of filamentous cyanobacteria and in many strains display positive phototaxis, which is important in the colonization of illuminated portions of the habitat by these photoautotrophic organisms. After entering the host, hormogonia revert to non-motile vegetative filaments, the differentiation of nitrogen-fixing heterocysts is observed, and vegetative cells show altered morphology compared with their free-living counterparts. The development of heterocysts after plant infection is essential for a functional nitrogen-fixing symbiosis (Santi et al., 2013; Rashid et al., 2015).

Regulation of nitrogenase activity in diazotrophs

The reaction catalyzed by the nitrogenase enzyme is an extremely energy-demanding process since reduction of 1 mol of N₂ requires 16 mol of ATP in vitro. Moreover, the relatively slow turnover time of the enzyme requires diazotrophs to synthesize large quantities of nitrogenase to use dinitrogen as a sole nitrogen source. In addition, the oxygen sensitivity of nitrogenase imposes considerable physiological constraints on diazotrophy as there is an obligation to protect the enzyme from oxygen damage. Therefore, the synthesis of both molybdenum and the molybdenum-independent nitrogenases is stringently regulated at the transcriptional level in response to the availability of fixed nitrogen and to environmental oxygen levels. The degree to which each stimulus affects transcription is characteristic of the particular diazotroph. In addition to regulation at the transcriptional level, nitrogenase activity is also subject to post-translational regulation in some diazotrophs (*Rhodospirillum rubrum*, *Rhodobacter capsulatus*, and *Azospirillum brasilense*). The necessity to respond to the concentrations of fixed nitrogen and external oxygen, and to provide sufficient energy for nitrogen fixation, imposes common regulatory principles among diazotrophs. However, there is considerable plasticity in the regulatory networks, which differ among microorganisms and are dependent on host physiology.

Transcriptional regulation

Regulation of nitrogen fixation is governed by several genes in response to the environmental signals of molecular oxygen and fixed nitrogen. The σ^{54} -dependent transcriptional activator NifA is the central key to this regulation (Fig. 3).

Nitrogen regulation

Diazotrophs can also access nitrogen through uptake of externally available nitrogen sources, which can include both low- and high-molecular-weight organic N sources. Given the energy costs of symbiotic nitrogen fixation, it is generally downregulated by increasing nitrogen availability, as diazotrophs use external nitrogen in favor of fixed nitrogen. Ammonium, the direct product of nitrogen fixation, is well known to inhibit nitrogen fixation and has been shown to inhibit nitrogenase synthesis at the transcriptional level through the regulation of NifA expression or modulation of its activity. NifA (a member of the bacterial enhancer-binding family) is the master regulator of nitrogen fixation in diazotrophic Proteobacteria which acts as a transcriptional activator responsible for control of all major *nif* gene cluster transcription to ensure that nitrogenase expression is stringently regulated by the demand for fixed nitrogen. In many diazotrophic Proteobacteria, expression of NifA is controlled by the

Fig. 3 Regulation of nitrogen fixation. Transcriptional control operates by a regulatory cascade with three levels: activation of NtrC by NtrB in response to low nitrogen, induction of *nifA* gene expression by phosphorylated NtrC, and induction of *nif* genes by NifA in *Klebsiella pneumoniae*. Transcription of *nifL-nifA* operon is not subject to nitrogen regulation in *Azotobacter vinelandii*. In both organisms NifA is active under conditions of nitrogen limitation. In *A. vinelandii* this is promoted by binding of 2-oxoglutarate to NifA, which prevents inhibition by NifL, and also by uridylylation of GlnK controlled by GlnD, preventing its interaction with NifL. By contrast, in *K. pneumoniae* GlnK is required to prevent interaction of NifL and NifA under nitrogen-limiting conditions. Oxygen regulates *nif* gene expression by affecting NifA activator either directly (*K. pneumoniae*) or through the NifL protein (*A. vinelandii*), and in some bacteria additional bicomponent systems like FixL/FixJ (*Sinorhizobium meliloti*, *Bradyrhizobium japonicum*) and RegS/RegR (*B. japonicum*) also control expression of *nifA* or microaerobic growth genes. In *Rhodobacter* and *Rhodospirillum*, nitrogenase activity is regulated by a switch-on/switch-off mechanism (posttranslational control) in response to oxygen and ammonium, which involves the DraT/DraG two component system.

two-component NtrB-NtrC nitrogen regulatory system in response to covalent modification and the ligand-binding state of the PII protein (GlnB) which provides global control in response to the nitrogen source (Fig. 3) (Dixon and Khan, 2004). This first level of the nitrogen regulatory cascade is absent in the aerobic nitrogen fixing soil bacteria *Azotobacter vinelandii* since NtrB-NtrC system is not required for activation of *nifLA* transcription.

In addition, the activity of NifA itself is stringently regulated either directly or indirectly by signal transduction protein (GlnK) (Fig. 3). In many cases, the nitrogen signal transduction mechanism involves direct interaction with PII protein. However, in some Proteobacteria, NifA activity is controlled by a partner protein NifL, which senses environmental cues and interacts with PII protein, to modulate NifA activity in response to the nitrogen status, providing a second level of the regulatory hierarchy. For example, in *A. vinelandii*, the non-modified form of GlnK is required for the formation of the inhibitory complex between NifL and NifA under nitrogen excess conditions, as opposed to *Klebsiella oxytoca*, where GlnK is required to relieve inhibition of NifA activity by NifL under nitrogen-limiting conditions (Dixon and Khan, 2004).

Oxygen regulation

Four proteins that regulate nitrogen fixation are oxygen/redox sensors: the histidine kinase FixL, the histidine kinase RegB, the anti-activator NifL and the activator NifA (which is only oxygen-sensitive in those diazotrophs that lack NifL) (Fig. 3) (Bueno Batista and Dixon, 2019).

In some rhizobia, the two-component FixL-FixJ system (Fig. 3) is involved in the low oxygen-dependent transcriptional control of nitrogen fixation genes. FixL protein contain N-terminal PAS domain which is commonly found in prokaryotic and eukaryotic sensors of oxygen. Low oxygen concentrations activate the oxygen sensor protein FixL, which in turn phosphorylates and thereby activates the transcriptional activator FixJ. The activated FixJ protein induces transcription of *nifA* and *fixK*, and the protein products of these genes induce the transcription of different genes encoding proteins involved in the process of nitrogen fixation.

In the free-living diazotrophs *Klebsiella pneumoniae*, *A. vinelandii*, and *Enterobacter cloacae*, which belong to the γ -Proteobacteria, NifA activity is not directly sensitive to oxygen. In these organisms NifA activity is regulated in response to molecular oxygen and combined nitrogen through a second regulator NifL; the *nifL* and *nifA* genes together form an operon (Fig. 3). In *Klebsiella*

pneumoniae, the expression of the *nifLA* operon itself is regulated by the nitrogen status of the cell, via the NtrB/NtrC two component regulatory system; in *A. vinelandii*, however, *nifLA* is expressed constitutively. The domain structures of NifL and FixL are analogous. The sensing method is different in each case, however, as the NifL PAS domain contains flavin-adenine dinucleotide whereas FixL contains a haem prosthetic group. The FAD-containing PAS domain of NifL is required for redox sensing and regulates the ability of NifL to inhibit NifA activity in response to the oxygen status. Inhibition of NifA activity by NifL occurs possibly via direct protein-protein interaction. In diazotrophic Proteobacteria that lack NifL, NifA proteins have a slightly different domain structure to those that are subject to NifL inhibition, containing an invariant Cys-X₄-Cys motif. The presence of these cysteine residues seems to correlate with the oxygen sensitivity of these proteins. Indeed, all of the conserved cysteines are indispensable for NifA activity, and metal ions are required for *in vivo* activity in *Bradyrhizobium japonicum*. This might suggest a model in which metal ion coordination to the cysteine residues controls the activity of these proteins in response to the redox status.

The global redox-responsive RegB-RegA two-component system (Fig. 3), directly regulates *nif* transcription in some diazotrophic members of the α -Proteobacteria. RegB is a histidine sensor kinase and contains a conserved cysteine residue. This conserved cysteine is essential for redox sensing and on oxidation. Phosphorylation of the response regulator RegA increases its DNA-binding activity, transcriptional modulation and interactions with other regulators. In *R. capsulatus*, RegA function in conjunctions with NtrC to indirectly activate nitrogenase synthesis by binding to and activating the expression *nifA2* promoter. In *B. japonicum*, homologs of RegB and RegA (known as RegS and RegR, respectively) have been shown to control *nifA* expression during the symbiosis.

Post-transcriptional regulation

In addition to regulation at the transcriptional level, nitrogenase activity is also subject to posttranslational regulation in a few free-living diazotrophs (*R. rubrum*, *R. capsulatus*, and *A. brasilense*). At least three different mechanisms, involving PII proteins (GlnB or GlnK), are known to switch-off nitrogenase activity under excess nitrogen conditions in Proteobacteria (Bueno Batista and Dixon, 2019). GlnB and GlnK are signal transduction proteins known to integrate various metabolic signals including the levels of glutamine, ADP, ATP, and 2-oxoglutarate to control both nitrogen fixation and nitrogen assimilation. The first mechanism involves rapid inactivation of nitrogenase Fe protein by ADP ribosylation, catalyzed by DraT (ADP-ribosyltransferase). This post-translational covalent modification can be reversed by another enzyme with opposing activity named DraG (ADP-ribosyl glycohydrolase) (Fig. 3). The activity of both enzymes is regulated by interaction with GlnB and GlnK proteins depending on the nitrogen status. Under excess nitrogen conditions, non-modified GlnB interacts with DraT-stimulating ADP ribosylation. In addition, GlnK mediates formation of a ternary complex between AmtB, GlnZ and DraG, that sequesters DraG to the membrane, inhibiting its ability to remove the covalent modification from nitrogenase. Under conditions of nitrogen limitation, the uridylylated forms of GlnB cannot interact with either DraT or DraG. Under these circumstances, DraT is inactive and DraG is active, leading to the removal of the ribosyl modification from the nitrogenase Fe protein, thus reactivating nitrogenase. A second mechanism for nitrogenase switch-off apparently involves inhibition of the Rnf1 electron transport system (encoded by *rnfABCDE*), which potentially provides a dedicated electron transfer pathway to nitrogenase in *A. vinelandii*. Genes encoding the Rnf1 complex are co-located with the *nifLA* operon in diverse diazotrophs. In *A. olearius* BH72, the interaction GlnK and the Rnf1 complex has been proposed to control electron transfer to nitrogenase. A third unknown mechanism involving GlnK and the ammonium transporter AmtB may be responsible for nitrogenase switch-off during ammonium upshift in organisms lacking both DraT-DraG and the Rnf1 electron transport system.

Nutrient exchange and symbiotic biological nitrogen fixation

The exchange of nutrients between a plant and a nitrogen-fixing microorganism is critical for symbiotic nitrogen fixation. In return for fixed nitrogen, the plant typically provides its bacterial symbiont with a carbon source and other crucial nutrients, depending on the intimacy of the symbiosis. Both organisms change their metabolic routines to accommodate to each other's needs, a process that is monitored and regulated by both partners (Fig. 4) (Mus et al., 2016).

Carbon metabolism

Nitrogen fixation is an energetically and, therefore, carbon expensive process and diazotrophs can only fix nitrogen when adequate supplies of carbon are available. Plant root exudates, carbon-rich secretions consisting of low-molecular-weight compounds such as sugars, organic acids, and mucilage are potential source of carbon capable of meeting energy demands of associative diazotrophs. During legume-*Rhizobium* symbiosis, the carbon supply, required to fuel nitrogenase activity in the bacteroid, is derived from plant photosynthate that is transported to the nodules via the phloem as sucrose. In nodule cells, sucrose metabolism releases hexoses that subsequently enter glycolysis to produce phosphoenolpyruvate, which in turn is converted to dicarboxylic acids. Dicarboxylic acids such as malate are assimilated by gluconeogenesis or catabolized via enzymes of the tricarboxylic acid (TCA) cycle to provide the reductant and ATP required for nitrogen fixation (Alemayehu et al., 2018). Several other compounds such as phosphorus, iron, and sulfur are made available to symbiotic microbes, especially in the case of endosymbionts, which rely on the host for all their essential nutrients. The exchange of metabolites between the plant and bacteroids does not happen freely but is facilitated by specialized transporters. Among these are genes encoding putative sugar transporters, amino acid transporters, and sulfate transporters.

Fig. 4 Associative nitrogen-fixing interactions carried out by a diverse array of free-living nitrogen fixers and symbiotic nitrogen-fixing associations performed by endophytic or endosymbiotic nitrogen fixers (e.g., *Rhizobia*). Associative nitrogen-fixing interactions is supported by root exudates compounds while symbiotic nitrogen fixing associations receive a constant supply of simple C compounds directly from the host plant. Oxygen concentration in the rhizosphere is highly variable and driven by soil structure and texture and respiration by microbes and roots. Conversely, symbiotic nitrogen fixers are supplied with oxygen at low concentrations by their host plant. Nutrients necessary to support associative nitrogen-fixing interactions must be acquired by the diazotroph from the soil. However, these nutrients are delivered to symbiotic nitrogen fixers by the host plant. Associative nitrogen fixers can access nitrogen via nitrogen fixation or through uptake of externally available nitrogen sources. The availability of external nitrogen sources inhibits the nitrogenase enzyme. Ammonium, the direct product of nitrogen fixation, released by associative nitrogen fixers is available to plants. All symbiotically fixed nitrogen is delivered to the host plant.

Nitrogen metabolism

The exchange of fixed nitrogen is another nutrient important for the symbiosis to be mutually beneficial. Specifically, bacterial nitrogen metabolism must be altered so that nitrogen is excreted rather than incorporated into the microbial biomass. The plant host appears to directly interfere with bacterial amino acid biosynthesis and thereby forces the release of nitrogen.

In nitrogen-fixing *Rhizobium* bacteroids, nitrogen metabolism is significantly altered during bacteroid differentiation, and ammonia assimilation is effectively shut via an unknown and presumably plant-regulated post-translational modification of the enzyme glutamine synthetase (GS). Ammonia produced by nitrogenase is delivered to the plant cell as NH_4^+ or NH_3 via passive diffusion or active transport involving transporter AmtB. Once inside the plant cell, ammonia is assimilated into amino acids mainly by the action of GS, glutamate synthase (GOGAT), and aspartate aminotransferase. The expression of genes encoding these enzymes is induced during nodule development (White et al., 2007).

In actinorhizal plant-*Frankia* symbiosis, the bacterial GS remains fully functional, but downstream components of amino acid biosynthesis are downregulated. Fixed nitrogen is released to the plant in the form of amino acids or amides. These are then broken back down to NH_4^+ , which is then assimilated by the actinorhizal host by the action of GOGAT (White et al., 2007).

In symbiosis with both *Azolla* and *Gunnera*, the cyanobacterial GS is downregulated (unlike in legume-*Rhizobium* symbiosis), resulting in ammonium release. This ammonium is subsequently assimilated by the GS-GOGAT system of the plant host. Unlike other cyanobacterial symbioses, in *Nostoc*-cycad associations, the GS-GOGAT system of *Nostoc* is not downregulated, and nitrogen is transferred to the host in the form of citrulline, glutamine, or both, depending on the cycad host (White et al., 2007).

Environmental factors influencing symbiotic biological nitrogen fixation

Biological N fixation relies on a delicate partnership between plant and bacterial species and is maximized when niche requirements are met for both species. Factors that limit plant health and photosynthetic capacity will likewise limit nitrogen fixation potential. However, even when optimal conditions are met for plant growth and development, the establishment of symbiotic association can be independently inhibited by factors including nutrient availability, moisture, soil pH, temperature, and oxygen status (Fig. 4) (Alemayehu et al., 2018).

Soil pH, moisture, temperature and light

Soil pH is likely to be highly variable in the rhizosphere and may be an important environmental control on symbiotic biological nitrogen fixation. Indeed, rhizobia growth, survival and abundance, in addition to their competitiveness in nodulation, are highly influenced by soil pH. Increased H^+ concentration and increased solubility of the toxic metal ions Al^{3+} , Cu^{2+} and Mn^{2+} are the primary causes of intercellular pH instability leading to growth inhibition in low pH soils. In low pH soil, nodule formation has been reported to be reduced by >90% and nodule dry weight by >50% in species such as soybean, pea, cowpea, *Medicago* and

lucerne. In common bean, low soil pH is reported to reduce the number, ultrastructure and weight of nodules, in addition to the nitrogenase activity. Nitrogen fixation is typically reported to be reduced in acidic soil, with molybdenum deficiency in low pH soil further hinders nitrogen fixation, as it is a key component of the nitrogenase enzyme complex. Low pH conditions also disrupt the signal exchange between the host plant and microsymbiont by reducing plant flavonoid secretion, decreasing *Rhizobia* *Nod* gene induction and restricting Nod factors and Nod metabolite excretion. Low pH conditions have also been shown to affect *Rhizobia* attachment to root hairs and root colonization, leading to reduced nodule formation.

The activity of diazotrophs is also controlled by other abiotic factors such as soil moisture content and ambient temperatures, which can promote or inhibit nitrogen fixation. For instance, sufficient moisture content is required for nitrogen fixation activity and has been put forward as a main driver of nitrogen fixation. Studies, which have been conducted in the high Arctic on free-living- as well as on moss and lichen-associated diazotrophs, have shown a strong moisture dependence of nitrogen fixation. Whereas mosses, lichens and free-living nitrogen fixers easily lose water under warm and dry conditions, diazotrophs associated with legumes should be able to remain active for longer exposed to the same conditions. As for all enzymatic processes, temperature is a key factor, affecting nitrogenase activity positively, with reported temperature optimums between 25 °C and 30 °C. Soil temperature also disturbs the fixation processes, as it can exceed 40 °C at 5 cm depth, imposing limitations on the biological nitrogen fixation and nodule viability in the soil (Hungria and Vargas, 2000). The soybean crop thrives under favorable temperatures from 25 °C to 30 °C during its developmental stages in the soil. In legumes, the optimal temperature for induction of biological nitrogen fixation ranges from 27 °C to 40 °C, although temperatures exceeding 37 °C cause the death of the rhizobia and some genetic changes, rendering them less efficient, when compared with the selected strains.

Another important factor controlling nitrogen fixation in cyanobacteria is light. Nitrogen fixation is energy “costly,” and energy in the form of photosynthates is required to sustain nitrogenase activity in autotrophs. Heterotrophic diazotrophs on the other hand have to cover their energy demand through the breakdown of organic matter. As for all enzymatic processes, temperature is a key factor, affecting nitrogenase activity positively, with reported temperature optimums between 25 °C and 30 °C.

Soil nutrient availability

Soil nutrient status has a tremendous influence on the symbiosis as well as independent growth and survival of both partners.

Several field studies also demonstrate that nodulation and nitrogen fixation can be inhibited by high field nitrogen levels. High levels of nitrate in or near the nodules inhibits nitrogenase activity through a feedback mechanism, thereby reducing nitrogen fixation. Above a certain concentration, excess nitrogen can inhibit nodule initiation entirely. Estimates for nitrogen levels that will eliminate nodulation vary widely from lower value of 50 kg/ha to high value of 120 kg/ha. Tolerance of nitrogen fixation to high soil nitrate levels varies across species and even among genotypes of the same species (Zahran, 1999). Ammonium, the direct product of nitrogen fixation, is well known to inhibit nitrogen fixation (see sections above “Transcriptional regulation” and “Nitrogen regulation”) and has been shown to inhibit nitrogenase synthesis at the genetic level through the regulation of *nifA* gene transcription. Expression of nitrogenase in symbiotic diazotrophs is fairly insensitive to ammonium because export of ammonium to their symbiont suppresses ammonium levels. The expression of *nif* genes in free-living diazotrophs is more sensitive to cellular ammonium levels.

The availability of phosphorus and micronutrients, including Fe, Mo, and V, is known to influence nitrogen fixation (Zahran, 1999). In low phosphorus-content soil, phosphorus has been shown to control the rates of heterotrophic biological nitrogen fixation and to limit biological nitrogen fixation in rhizobial symbioses. Phosphorus appears essential for both nodulation and nitrogen fixation, as phosphorus deprivation is often associated with decreased nodule tissue formation and low rates of nitrogen fixation. Legume-*Rhizobia* symbiosis requires micronutrients including boron, cobalt, copper, iron, manganese, molybdenum, nickel, selenium, and zinc, sometimes at higher rates than the plant or free-living bacteria require alone. Iron, sulfur, molybdenum and vanadium are essential components of nitrogenases (Nif, Vnf, and Anf) (see section above, “Biological nitrogen fixation and nitrogenase enzymes”), and the availability of these trace metals may be critical for the nitrogen cycle of terrestrial ecosystems.

Oxygen status

Oxygen irreversibly inhibits nitrogenase and so can greatly influence the efficiency of symbiotic nitrogen fixation. Therefore, diazotrophs must employ protection mechanisms to maintain nitrogen fixation when oxygen is present. This includes avoidance of oxygen via growth strategy, spatial or temporal isolation of nitrogenase from oxygen, and production of biofilms as oxygen diffusion barriers. Diazotrophs can also remove oxygen by increasing substrate utilization, which increases respiration rates, thereby decreasing oxygen concentrations.

Microaerobic conditions favorable to nitrogenase are established in legume, *Parasponia*, and actinorhizal nodules by various mechanisms that include: O₂ diffusion resistance in outer cell layers of nodules; binding and transport of O₂ by leghemoglobins in infected cells of the nodule interior; restriction of oxygen diffusion into bacteria by external mucilage; rapid consumption of O₂ by bacteria and plant mitochondria. The crucial role of leghemoglobins was demonstrated for nitrogen fixation in legume root nodules (Ott et al., 2005). Leghemoglobins accumulate to millimolar concentrations in the cytoplasm of infected plant cells prior to nitrogen fixation and are thought to buffer free oxygen in the nanomolar range as low as 20–50 nM, avoiding inactivation of oxygen-labile nitrogenase while maintaining high oxygen flux for respiration. Rhizobia respond to the microaerobic conditions in the nodule through a complex signaling cascade involving multiple O₂ sensors (FixL/FixJ, hFixL/FxkR, FnrN), and rhizobial regulatory mechanisms insensitive to O₂ tension are essential for successful differentiation into bacteroids and the establishment of a productive symbiosis (Inomura et al., 2017).

Oxygen concentrations in the rhizosphere are dynamic and can range from near 0% (anaerobic) to 21% (ambient). However, because of the diversity of diazotrophs present and potentially active in the rhizosphere, it is difficult to pinpoint one optimal oxygen concentration for biological nitrogen fixation. For example, Inomura et al. (2017) demonstrated that oxygen concentrations around 3% resulted in significantly greater nitrogenase activity by the plant-associated aerobic diazotroph *A. vinelandii*. Various mechanisms for oxygen protection of nitrogenase in *A. vinelandii* have been proposed (Maier and Moshiri, 2000). These include a high respiratory rate involving a specialized cytochrome that keeps oxygen levels low inside the cell, a protein that binds and protects nitrogenase (but renders it temporarily inactive) under conditions of oxygen stress, and the production of an alginate capsule that presumably slows oxygen diffusion into the cell. Similar mechanisms have been described for *Gluconacetobacter*.

Cyanobacteria have evolved several mechanisms to protect nitrogenase from oxygen toxicity (Stal and Krumbien, 1985). These strategies involve spatial or temporal separation of photosynthesis and nitrogen fixation. Some filamentous cyanobacteria, such as *Nostoc* and *Anabaena*, develop specialized non-photosynthetic cells, called heterocysts, where nitrogen fixation occurs. Heterocysts lack the oxygenic photosystem II and are able to maintain microaerophilic conditions by their thick cell walls acting as an oxygen barrier and through active respiration. Other cyanobacteria have the ability to carry out photosynthesis and nitrogen fixation in the same cell by fixing nitrogen at a time when photosynthesis is depressed, typically at night.

Mycorrhizal interaction

In natural environments, legume roots form tripartite interactions, and are simultaneously colonized by both arbuscular mycorrhizal fungi and *Rhizobia*. Various studies have demonstrated that tripartite interactions improve plant productivity, seed yield, phosphorus and nitrogen acquisition, and photosynthetic rates (Bournaud et al., 2018). Arbuscular mycorrhizal fungi are known to have significant positive effect on biological nitrogen fixation by direct or indirect interaction with nitrogen-fixing microorganisms. Indeed, arbuscular mycorrhizal fungi can facilitate the colonization of legume roots by symbiotic nitrogen-fixing bacteria and have been shown to increase the biological nitrogen fixation by root nodules by at least 50%, providing their hosts with elements that are essential for nitrogen fixation, including phosphorus, zinc, iron, manganese and molybdenum.

The importance of nitrogen-fixing symbioses to soil fertility

Nitrogen input through biological nitrogen fixation is approximately 122 million tons of nitrogen per year of which 55–60 million tons is fixed by agricultural crops. The potential of biological nitrogen fixation providing nitrogen in ecosystems is increasingly being exploited in agricultural practices, mostly through legume cultivation (e.g., soybean, lupin, alfalfa, chickpea, cowpea). The nitrogen fixed by legumes can also represent an important renewable source of nitrogen for agricultural soils. However, the net inputs of fixed nitrogen into soils depend upon the amounts of nitrogen fixed relative to the amounts of nitrogen removed in the protein-rich legume products which can represent between 45% and 75% of the nitrogen in the above-ground biomass of crop legumes (Peoples et al., 2009). The residual contribution of fixed nitrogen into agricultural systems following legume cropping might be then relatively small. Despite this, the yields of crops are often greater when legumes are included in cropping sequences than when they are not. Several non-leguminous plants, mainly cereals (maize, barley, sugarcane), have also developed multiple strategies in association with diazotrophs (*Azospirillum*, *Azotobacter*, *Pseudomonas*, *Bacillus*) to cope with nitrogen deficiency. The most sophisticated associations are root nodule endosymbioses between *Frankia* and actinorhizal plants, *Rhizobium* and *Parasponia* sp., and cyanobacteria that associate with *Gunnera* sp.

In addition to their nitrogen-fixing abilities, diazotrophic bacteria can also solubilize phosphorus so that it is available to the plant. They can also provide specific iron chelators (siderophores) and synthesize phytohormones (such as cytokinins, gibberellins, indole-3-acetic acid), that promote plant growth and yield and cause positive changes in soil structure and microbial community. Many diazotrophic strains belonging to *Rhizobia*, *Azotobacter*, *Azospirillum*, *Pseudomonas*, *Klebsiella*, and *Bacillus* genera were reported to enhance the plant growth and grain yield of chickpea, common bean, pea, wheat and rice through phytohormones, siderophores and secondary metabolites production. *Rhizobia* has also been reported to act as biocontrol agents against pathogenic fungi through hydrocyanic acid, antibiotics and/or mycolytic enzymes production.

Strategies for engineering symbiotic nitrogen fixation

In agriculture nitrogen limitation is circumvented by application of fertilizers derived from the Haber-Bosch process of inorganic nitrogen-fixation. Despite the significant contribution of synthetic fertilizers, nitrogen requirements for food production increase from year to year, while the overuse of agrochemicals compromise soil health and agricultural sustainability. With the increasing global population and problems caused by unintended nitrogen wastage and pollution, more sustainable ways of managing the nitrogen cycle in soil and utilizing biological nitrogen fixation have become imperative. Symbiotic nitrogen fixation is largely limited to legumes in agricultural systems, but there are a number of microorganisms, including some diazotrophs, that inhabit the rhizosphere of other crop plants, some of which have been shown to enhance plant growth. One of the greatest challenges in agriculture is supplying sufficient plant-available nitrogen to cereal crops, which provide 45% of the world's dietary energy consumed directly by humans in addition to providing feed for animal agriculture and a feedstock for bio-based fuel production and manufacturing. Therefore, there is growing interest in increasing the contribution of biological nitrogen fixation to the growth of crop plants in agriculture.

Fig. 5 Main approaches to engineer or improve biological nitrogen fixation in cereals: 1-Engineer the legume symbiosis into cereals; 2-Engineer expression of nitrogenase in plant organelles; 3-Engineer nitrogen fixation in plant colonizing bacteria (Oldroyd and Dixon, 2014; Rogers and Oldroyd, 2014; Mus et al., 2016; Pankiewicz et al., 2019).

Three approaches have arisen with the common goal of engineering biological nitrogen fixation in plants, either by (1) engineering the legume symbiosis into cereals or by (2) transferring the components required for nitrogenase activity into plant organelles such as chloroplast and mitochondria, or by (3) involving the enhancement of naturally occurring plant-associated diazotrophs by generating strains that release fixed nitrogen to benefit the crop (Fig. 5). Although the two first approaches are reliant on complex synthetic biology strategies, which will probably take considerable time to develop as viable products for farmers, the third approach could potentially provide a means to reduce the use of synthetic nitrogen fertilizers thus providing a short-term solution to the nitrogen crisis.

However, the ability to stringently control this association and eliminate escape mutants and DNA release to the environment will be an aspect to take into consideration when developing strategies and tools for engineering symbiotic nitrogen fixation.

Engineering the legume symbiosis into cereals

Most land plants, including cereals, can form arbuscular mycorrhizal associations but are unable to form nitrogen-fixing root nodule symbioses. Several components of the legume symbiotic signaling (SYM) pathway also play a role in the arbuscular mycorrhizal symbiosis (Oldroyd and Dixon, 2014). Since cereals contain the SYM pathway for arbuscular mycorrhizal associations, nodulation could be established in them by engineering the perception of rhizobial signaling molecules to activate this pathway, as well as by engineering its outputs of activation into an oxygen-limited nodule-like root organ for nitrogen fixation. Engineering synthetic symbiosis in cereal crops involves the manipulation of both nitrogen-fixing microorganisms and nitrogen fixation associations to exchange appropriate signals to establish successful colonization and nitrogen fixation. In this approach, plants can be engineered to secrete a specialized carbon source that specifically enhances the competitiveness of newly introduced nitrogen-fixing microbes in the rhizosphere. However, the availability of a wide range of well characterized promoter elements in cereals poses a challenge in engineering symbiotic nitrogen fixation in cereals. Indeed, the use of the same promoter to express multiple genes in transgenic plants can induce gene silencing. The construction of large multigene synthetic cassettes and the persistent need to improve cereal transformation technology cause other immediate barriers to engineer nitrogen-fixing capability in cereal crops.

Engineering expression of nitrogenase in organelles of plants

The introducing nitrogenase-encoding bacterial *nif* genes into plants is a direct approach to engineer nitrogen fixation in non-legumes. However, the complexity of nitrogenase biosynthesis and the sensitivity of nitrogenase to oxygen present a significant challenge. Extensive genetic and biochemical studies have identified the common core set of genes/gene products required for functional nitrogenase biosynthesis (Mus et al., 2016). In addition, plastids and mitochondria offer potential subcellular low-oxygen environments to express active nitrogenase in plants, making this engineering strategy feasible.

Engineering nitrogen fixation in plant colonizing bacteria

Two distinct approaches have been proposed to enhance pre-existing interactions between plants and bacteria, either engineer increased colonization between plants and highly efficient nitrogen-fixing microbes or engineer transfer of efficient nitrogen fixation into bacteria that already associate closely with cereals (Fig. 4) (Geddes et al., 2015). During the last 40 years, there has been a rapid expansion in genetic engineering tools, and advances made in the field of synthetic biology (precision expression control, multi-gene and assembly, synthetic regulation) may aid the engineering and transfer the supporting traits for nitrogen fixation. However, the factors that are required for nitrogen fixation are more defined than those that govern colonization. Therefore, the approach of engineering robust colonizers that fix nitrogen has arguably more practical merit.

The large nitrogen fixation island from *Pseudomonas stutzeri* was successfully transferred to the aerobic associative bacterium *Pseudomonas protegens* Pf-5, conferring the ability to grow micro-aerobically using N_2 as a sole nitrogen source. Moreover, inoculation of Arabidopsis, alfalfa, tall fescue, and wheat with transgenic *P. protegens* resulted in significant growth promotion effects compared to the near-isogenic wild-type under nitrogen-limited conditions (Setten et al., 2013). Although engineering new more-robust microbe-mediated nitrogen fixation associations requires many genes that are tightly regulated in their native host and are sensitive to environmental conditions that are not desirable in agriculture (e.g., repressed by high ammonia). To overcome this issue, it requires either transferring the pathway from one organism to another or un-silencing a cluster in a native host. However, the pathway is very sensitive to small changes in gene expression, and the regulatory control in many organisms is not well characterized. In addition, the microbe needs to establish a symbiotic relationship with the crop, which either requires engineering the plant or using endophytes, for which there may be few genetic tools (e.g., transposon mutagenesis).

Ammonia release by bacteria is another critical attribute for translating engineered nitrogen fixation by bacteria into nitrogen assimilation by plants (Geddes et al., 2015). The misregulation of the *P. stutzeri* *nif* cluster in *P. protegens* Pf-5 resulted in significant ammonia release by the bacteria. Mutations of the key regulators *nifA* or *nifL* have also resulted in ammonium excretion in *A. vinelandii*. The deletion of two ammonium transporters, encoded by *amtB1* and *amtB*, enhanced ammonia secretion in *P. stutzeri* that was further increased when combined with expression of *nif* genes from a constitutive promoter. Ammonia release by an *A. brasilense* glutamate synthetase (*glnA*) mutant may have increased growth of wheat under nitrogen-limited conditions. *A. vinelandii* with combined *nifL* and glutamine synthetase active site mutations also showed high ammonia release.

A significant challenge of transferring nitrogen fixation to aerobic microorganisms is that the nitrogenase is irreversibly inactivated by oxygen. Some aerobes such as *A. vinelandii* and *Azorhizobium caulinodans* are capable of free-living nitrogen fixation and have sophisticated mechanisms of oxygen protection. This is thought to be through maintaining high rates of oxygen consumption at the cell membrane via respiration, but it may also involve an alginate oxygen diffusion barrier and conformational protection of nitrogenase by interaction with a specific iron-sulfur protein termed the Shethna protein. Efforts are in progress to transfer oxygen protection systems, like the Shethna protein of *A. vinelandii*, to other diazotrophs.

Conclusions

The association of plants with nitrogen-fixing bacteria range from casual coexistence in the same environment to complex intracellular symbioses and allow plants to flourish in situations in which plant-assimilable nitrogen is limiting or even absent. The establishment and functioning of an effective symbiotic nitrogen fixation are dependent on genetic determinants in both plant and bacteria which are controlled by intricate regulatory mechanisms to ensure that fixed nitrogen is readily assimilated into biomass and not released to the environment. Symbiotic nitrogen fixation is restricted mainly to legumes in agricultural systems, and there is considerable interest in exploring whether similar symbioses can be developed in non-legumes, which produce the bulk of human food. Therefore, the creation of artificial symbioses or associations between diazotrophs and crops has been a primary goal in agriculture to reduce the demand for chemical nitrogen fertilizers, to improve crop yields, promote soil fertility, and reduce the environmental impacts of chemical fertilizer application.

Abstract

Non-symbiotic nitrogen fixation (NS-N₂ fixation) is the microbially-catalyzed conversion of dinitrogen gas to ammonia in the absence of a plant symbiont. A wide range of Bacteria and Archaea are capable of NS-N₂ fixation, although Phyla Proteobacteria and Cyanobacteria are often the most abundant NS-N₂ fixing microorganisms present in soils. NS-N₂ fixation rates vary both seasonally and geographically, depending on soil physicochemical conditions, identity of overlying plants, and microbial community composition. This process can be an important source of N to ecosystems. In agriculture, NS-N₂ fixation rates can potentially be enhanced by optimizing physicochemical and biological conditions for NS-N₂ fixation, which may include customized plant- NS-N₂ fixing microorganism combinations.

Key Points

- Non-symbiotic nitrogen fixers contribute the nitrogen fixed to many ecosystems.
- A wide and diverse array of microbial taxa are capable of Non-Symbiotic (NS) Nitrogen fixation, although many soils are dominated by organisms in Phylum Proteobacteria.
- Ideal conditions for NS-N₂ fixation include low soil nitrogen, high soil carbon, low oxygen, and high soil moisture.
- Conditions suitable for NS-N₂ fixation are found in many ecosystems.
- Future research priorities should include better annual or seasonal estimates of NS-N₂ fixation, improved characterization of the plant-N₂ fixing microorganism relationship, and identification of functionally active taxa.
- Stimulating NS-N₂ fixation in agricultural fields may improve sustainability by reducing reliance on synthetic fertilizers.

Introduction

Nitrogen (N) is an essential element for all organisms to synthesize proteins and DNA; it is one of the most abundant elements in organisms, after carbon (C), oxygen (O₂), and hydrogen. Because of the high demand for N, it is often in short supply in soils and is the nutrient that most often limits growth of terrestrial vegetation. Prior to the development of synthetic N fertilizer, the primary source of N to terrestrial ecosystems was biological N₂ fixation, the microbial catalysis of dinitrogen gas (N₂) into biologically available ammonia (NH₃).

N is abundant on Earth, with 78% of the atmosphere containing N₂ gas. This N is mostly unavailable, though, because its triple bond is difficult to break. N₂-fixing microorganisms break the triple bond with the nitrogenase enzyme and high energy inputs, in the form of ATP ($\text{N}_2 + 8\text{H} + 8\text{e}^- + 16\text{ATP} + \text{Nitrogenase} \rightarrow 2\text{NH}_3 + \text{H}_2 + 16\text{ADP} + 16\text{Pi}$). Some N₂-fixing microorganisms form a symbiosis with plants where the plants provide energy, as C, in exchange for N from the N₂ fixed. Well-known N₂-fixing symbioses include legumes (partnered with members of the Rhizobiales), and actinorhizal plants, such as alder, (partnered with *Frankia*). However, a wide array of Bacteria and some Archaea can fix N₂ without a symbiont, a process known as non-symbiotic N₂ fixation (NS-N₂ fixation). NS-N₂ fixation occurs across a wide variety of habitats, with a range of non-leguminous plants, cereals and grasses and NS-N₂ fixing organisms greatly outnumber symbiotic N₂ fixing bacteria (Gaby and Buckley, 2011).

The term NS-N₂ fixation includes three groups of microorganisms: (i) free-living N₂ fixing organisms (habitats include the bulk soil, decomposing plant residues, soil aggregates, and termite habitats), (ii) associative N₂-fixing organisms (habitats include the roots and rhizosphere of non-legume plants), and (iii) endophytic N₂ fixing microorganisms, that live inside growing plants.

Ecology of NS- N_2 fixation

The nitrogenase enzyme catalyzes N_2 fixation and all known N_2 -fixing organisms contain the nitrogenase enzyme complex (Fig. 1). This complex has three isozymes, characterized by the transition metal present at the active site. The molybdenum (Mo)-nitrogenase is most common, but vanadium (V) and iron (Fe)-only nitrogenases also occur and are often referred to as alternative nitrogenases. N_2 -fixing organisms with alternative nitrogenases are mostly found in Mo-limited soils. In addition to the transition metal, all nitrogenases contain phosphorus (P) and Fe.

Nitrogenase activity demands large amounts of ATP (energy) but the enzyme is inactivated by O_2 . Because of these requirements, N_2 fixation generally occurs where there is an abundant supply of energy (C for heterotrophs, sunlight for photoautotrophs) and sufficient metals and P for nitrogenase synthesis. In addition, N_2 fixation tends to occur where N is limiting because when N is abundant, it takes less energy to scavenge for N than to fix it.

N_2 -fixing microorganisms, also known as diazotrophs, have been found in a wide array of soils and other environments. Within the soil environment, they have been found in both bulk and rhizosphere soil, on and within roots, and in decomposing residues.

Fig. 1 A conceptual diagram highlighting the diverse set of microsites that can support Non-Symbiotic N_2 fixation and its role in the soil N cycle. (1) A diverse array of bacterial genera have been found in the rhizosphere and endophytic environment of a variety of cereals and other plants; the amount of N_2 fixation in the field environment is yet to be properly quantified, (2) A significant amount of N_2 fixation has been shown to occur in the below- and above-ground plant environments with sugarcane, (3) fresh decomposing residues, especially with wide C:N ratios, provide optimal conditions for N_2 fixation, (4) stable aggregates not only provide protective sites for free-living N_2 -fixing bacteria but also provide the required low oxygen conditions for nitrogenase activity, and (5) a diverse group of microflora in termite guts and nests possess *nifH* genes that show potential for N_2 fixation in natural environments mainly in semi-arid and arid ecosystems (Modified from Roper MM and Gupta VSR (2016) Enhancing Non-symbiotic N_2 fixation in Agriculture. *The Open Agriculture Journal* 10: 7–27. <https://doi.org/10.2174/1874331501610010007>). Details of the mechanism for N_2 fixation and nitrogenase involvement in diazotrophs is adapted from and Aasfar A, Bargaz A, Yaakoubi K, Hilali A, Bennis I, Zeroual Y, Kadmiri IM (2021) Nitrogen fixing *Azotobacter* species as potential soil biological enhancers for crop nutrition and yield stability. *Frontiers in Microbiology* 12: 628379. <https://doi.org/10.3389/fmicb.2021.628379>.

Diazotrophs also live on leaf surfaces (the phyllosphere), in termite mounds and guts, and within other animals, including marine clams (Table 1; Fig. 1).

In soils, N_2 fixing organisms are a source of N for the ecosystem, but their interactions with other organisms are somewhat uncertain. Newly-fixed N has been found in a wide variety of non-leguminous and non-actinorhizal terrestrial plant species (Table 1). The relationship between plants and NS- N_2 -fixing microorganisms is not yet defined, but three potential relationships exist (Roley, 2021). First, plant benefits may be incidental, with diazotrophs fixing N solely for their own needs and the fixed-N cycling rapidly through the soil to be taken up by plants. Second, plants and diazotrophs may have a mutualistic relationship, in which plants exude carbohydrates or other materials to attract diazotrophs, and the plant and the diazotroph exchange materials. Third, plants may have a predatory relationship with microbes, in which they excrete oxidative species that remove the Fixed-N from diazotrophs. The exact nature of the relationship likely varies with host plant, diazotroph species and possibly with physicochemical conditions.

Likewise, the relationship of N_2 -fixing endophytes within the plant remains poorly defined. A diverse and abundant N_2 -fixing community has been found inside plants (Moyes et al., 2016). In some cases, these organisms clearly provide Fixed-N to the plant. In other cases, they provide plant growth-promoting benefits, in addition to or instead of, N_2 fixation, such as phytohormone and vitamin synthesis and improved nutrient uptake (Dobbelaere et al., 2003). But in other cases, the functional role of the N_2 -fixing organisms is unclear. Some diazotrophs in plant tissues could be there incidentally, moving into plant tissues via the transpiration stream without providing benefits, while others could be recruited by the plant. Several species of termites acquire N by hosting NS- N_2 fixing bacteria in their gut. Fixation rates and diazotroph abundance are highest in the workers and species with an N-poor diet (i.e., wood-feeding (N-poor) compared to dung-feeding (N-rich) species).

The transfer of Fixed-N to plants depends upon whether fixation occurs in the soil or the endosphere. Nitrogen fixed in the soil needs to be released from microbes prior to plant uptake. N release can occur via excretion (Bageshwar et al., 2017) or upon cell death and subsequent decomposition. The released N is subjected to N cycling processes (Fig. 1) (Aasfar et al., 2021), whereas the N fixed by endophytic diazotrophs can be directly available to the host plant. Direct provision of N from diazotrophs to plants may occur in the rhizosphere, likely in exchange for C, but this has yet to be confirmed by observation.

Significance of NS- N_2 fixation in soils and terrestrial environments

A growing body of evidence suggests that NS- N_2 fixation is a significant contributor to the N cycle in many ecosystems. In general, NS- N_2 fixation inputs are greatest where N availability is low and the C:N ratio is high. These conditions, along with NS- N_2 fixation, are present in all ecosystem types (agricultural fields, grasslands, forests, deserts), although inputs from fixation vary tremendously within and among ecosystems (Fig. 1, Table 1).

N_2 fixation is a tantalizing alternative to fertilizer addition in sugarcane and cereal cropping ecosystems; hence, it has been studied extensively in these systems. Supplemental N (as synthetic fertilizer or organic N) is typically used on these crops, but some of the added N will be removed via leaching, denitrification, and immobilization before it can be used by the crop. As a result, during peak N demand, N requirements can exceed supply from N mineralization and N fertilizers. Sugarcane has particularly high NS- N_2 fixation rates, receiving more than half of its N from endophytic diazotrophs (roots, stems, and leaves), with rates as high as $150 \text{ kg N ha}^{-1} \text{ year}^{-1}$ (Boddey et al., 2003). Furthermore, in agricultural soils with a lower level of fertility and organic matter, e.g., in southern and western Australia, India, Africa and Mediterranean regions, non-leguminous crops would benefit from increased N inputs from NS- N_2 fixation.

NS- N_2 fixation rates are generally smaller in cereal crops, but are still of agronomic significance. Globally, N-fertilized rice, wheat, and maize obtain up to 24% of their N from NS- N_2 fixation (Ladha et al., 2016). Rice paddies offer ideal conditions for fixation; the water-logged soils are low in O_2 and high in C. Rice also harbors a diverse community of diazotrophic endophytes (Minamisawa et al., 2005); however, inoculation with known active NS- N_2 -fixing organisms increases growth rate, grain yield, and protein content (Fig. 2) (Gaby and Buckley, 2014). Cyanobacteria and other photosynthetic NS- N_2 -fixing microorganisms inhabit rice paddies, fixing N that cycles through the soil and into rice. Wheat is grown in drier upland soils, but still receives agronomically significant levels of N from NS- N_2 fixation ($10\text{--}40 \text{ kg N ha}^{-1} \text{ year}^{-1}$, Ladha et al., 2016). NS- N_2 fixation likely contributes 29–92% of N nutrition in ancient Mexican maize land races (Van Deynze et al., 2018).

In croplands, NS- N_2 fixation has generally been measured in the rhizosphere, but it also occurs in association with crop residues, which contain large amounts of C. Conservation agricultural practices, which leave crop residues on the field, may increase N inputs from NS- N_2 fixation, particularly during non-crop periods. For example, residue NS- N_2 fixation contributed $<10 \text{ kg}$ to 38 kg N ha^{-1} during non-crop periods in southern and eastern Australia (Gupta et al., 2006).

Grasslands vary widely in their NS- N_2 fixation inputs (Table 1). In tropical grasslands, the overlying species appears to be important, with rapidly-growing species such as bahiagrass accumulating up to $37 \text{ kg N ha}^{-1} \text{ year}^{-1}$ from fixation. Slow-growing species, such as *Aristida laevis*, accumulate much less N from fixation ($<10 \text{ kg N ha}^{-1} \text{ year}^{-1}$), but still receive up to a third of their annual N needs from NS- N_2 fixation (Marques et al., 2017). In temperate grasslands, mass balance estimates are as high as $54 \text{ kg N ha}^{-1} \text{ year}^{-1}$ (Chapman et al., 1949), but estimates from laboratory incubations are often much lower, $<10 \text{ kg N ha}^{-1} \text{ year}^{-1}$. The discrepancy in rate measurements could be due to strong spatial or temporal variability: N_2 fixation may occur episodically, with occasional bursts of N_2 fixation activity responsible for most fixation on an annual scale (Roley et al., 2019). Although NS- N_2 fixation has been reported in the phyllosphere of perennial grasses, their contribution to overall plant N nutrition is not known (Gupta et al., 2019).

Table 1 Examples of non-symbiotic N₂-fixation and diazotroph taxa in different habitats.

System	Location	Common members/groups	Function (N ₂ -fixed)	References
Temperate grasslands	Rhizosphere	α -, β - and δ -Proteobacteria	4–54 kg N ha ⁻¹ year ⁻¹	Roley et al. (2019) and Jesus et al. (2016)

Fig. 2 Field experiments evaluating the benefits from endophytic N_2 -fixing inoculant *Azotobacter chroococcum* (Avi2) in rice crop var. Naveen at ICAR-NRRI, Cuttack in India (Kumar et al., 2021).

Forests appear to be particularly adept at N_2 fixation. NS- N_2 fixation has been measured in temperate deciduous and coniferous forests across a wide geographic range including most continents. Rates of up to $62 \text{ kg N ha}^{-1} \text{ year}^{-1}$ have been reported, with the highest rate in red pine in North America (Bormann et al., 2002). Similarly, NS- N_2 fixation in tropical rainforests ranges from 0.1 to $60 \text{ kg N ha}^{-1} \text{ year}^{-1}$ (Reed et al., 2011). Tropical forest soils are often highly weathered, and species that can fix their own N have a competitive advantage because they can harness more resources to extract P and micronutrients from the depleted soils. In forests, NS- N_2 fixation has primarily been measured in soils, but there is also evidence for fixation by needle endophytes (Moyes et al., 2016).

In deserts, biological soil crusts are an important source of N. The crusts occupy inter-plant spaces over the desert soil and consist of an array of microbial taxa, mostly in the Phyla Cyanobacteria and Proteobacteria (Pepe-Ranney et al., 2016). N_2 fixed in these crusts percolates downward to the soil and is a key N input, with contributions of up to $13 \text{ kg N ha}^{-1} \text{ year}^{-2}$ (Reed et al., 2011). NS- N_2 fixation also occurs in desert soils, in the absence of crusts, and can account for nearly 20% of the total soil N pool (Miao et al., 2020).

Nitrogenase and diazotroph communities

Diazotrophs are microbial taxa that contain the *nifH* gene, which codes for nitrogenase. The *nifH* gene is widespread across the Bacteria (heterotrophic and autotrophic) and Archaea, which demonstrates the adaptability of diazotrophs to a wide range of conditions and locations.

More than 50 species of diazotrophs have been cultured from soil and plant environments. Some of the extensively studied free-living bacterial species include *Azospirillum brasilense* (aerobe), *Azotobacter vinelandii* (an obligate aerobe), *Gluconacetobacter diazotrophicus*, *Herbaspirillum* sp., and *Klebsiella pneumoniae* (facultative anaerobes), *Clostridium pasteurianum* (an obligate anaerobe), *Rhodobacter capsulatus* (a photosynthetic bacterium) and various *Anabaena* and *Nostoc* species (heterocyst-forming cyanobacteria). Culturable taxa have been used in laboratory experiments that addressed the effects of environmental conditions (e.g., O_2 concentration, C sources, nutrients, temperature) on NS- N_2 fixation. A number of diazotroph cultures are available for use in sugarcane and rice fields, including *Azospirillum brasilense*, *Azotobacter chroococcum*, *A. vinelandii* and Cyanobacteria (Kumar et al., 2021, Fig. 2). However, most NS- N_2 fixing organisms are difficult to culture on artificial media. Our knowledge of their existence mainly comes from studies that use molecular techniques.

The nitrogenase enzyme complex is encoded by *nifH*, *nifD* and *nifK* genes, although the *nifH* gene is used as the signature gene for molecular diversity studies. The phylogenies of *nifD*, *nifK*, *nifE* and *nifN* appear to agree with *nifH*-based nitrogenase clusters, suggesting that the use of *nifH* is justified. Five major clusters with homology to *nifH* have been described, based on the *nifH* sequences available in public databases (Gaby and Buckley, 2011). Aligned sequences in such databases are required for

Fig. 3 The phylogenetic tree of all *nifH* homologs in the database. Red branches are low G + C sequences. Major phylogenetic groups are labelled. There are 7030 sequences (21.35% of the total database) in *nifH* cluster III and subcluster IA, the clusters that contain primarily obligate anaerobes. There are 24,799 sequences (75.31%) in *nifH* Cluster I, which mainly contains members of Proteobacteria, Firmicutes, and Actinobacteria (aerobic and facultative anaerobes). The database also contains 578 sequences (1.76%) in *nifH* Cluster II, which comprises the iron-dependent alternative nitrogenase cluster and obligate anaerobes including methanogenic Archaea, and 524 sequences in cluster IV which contains genes not functionally associated with nitrogenase. From Gaby JC, Buckley DH (2011 and 2014) A global census of nitrogenase diversity. *Environmental Microbiology* 13(7): 1790–1799. <https://doi.org/10.1111/j.1462-2920.2011.02488.x>.

phylogenetic and diversity analyses and for designing PCR probes for taxa and functional gene abundance. The diversity of diazotrophs, based on *nifH* sequence homology, is not distributed evenly across phylogenetic groups or environments and a majority of the soil *nifH* diversity is still undiscovered, particularly the anaerobic taxa (Gaby and Buckley, 2011).

The use of *nifH* gene-based analysis has provided a more complete picture of diazotrophic community composition and diversity and has expanded the list of known environments for NS- N_2 fixing microorganisms. Sequencing analysis places the *nifH* gene in phylogenetically diverse groups of Bacteria and Archaea. Based on the *nifH* gene homologs, diazotrophs are divided into 5 phylogenetic clusters (Fig. 3). In soils, most taxa are often in Phylum Proteobacteria. Alpha (α), beta (β), gamma (γ), and delta (δ) Proteobacteria are all common, with α -Proteobacteria often dominating. Within the α -Proteobacteria, Order Rhizobiales are most widely found. Other common phyla include Cyanobacteria, particularly in soil crusts. At the class, order, and genus-level, there is tremendous among-site variation, with that variation driven by physicochemical and biological factors. Nonetheless, there are some genera that show up in a variety of environments, including *Bradyrhizobium*, *Geobacter*, *Gluconacetobacter*, *Azospirillum*, *Azoarcus* and *Burkholderia*.

The composition of NS- N_2 fixing communities is shaped by physicochemical factors, including pH, soil texture, and nutrient availability. Soil management, which includes tillage type, plant type, and chemical application, also influences the NS- N_2 fixer community, likely through physicochemical factors. Bacterial phylotype diversity and richness are maximized at circum-neutral pH. In general, fertilizer addition reduces the abundance and diversity of diazotrophs (Ouyang et al., 2018), while organic matter inputs increase diversity and abundance, most likely by increasing the C:N ratio. Conversion to row crops reduces microbial biomass and changes the diazotrophic community, presumably as a result of the numerous plant and physicochemical changes associated with row crop conversion. The diversity of diazotroph communities has a significant relationship with the particulate organic carbon and water-soluble organic C to N ratio in soil. Agricultural pollution reduces diazotroph diversity and alters community composition (Jing et al., 2015). At the field and regional scale, management and plant type drive diazotroph community composition, whereas on a continental scale, climate and soil properties are the principal drivers.

Diverse and abundant communities of diazotrophs have been found in the above-ground plant parts (phyllosphere) of a variety of annual and perennial crops. Phyllosphere diazotroph community composition can vary with plant genotype and can be distinct from the root diazotrophic community (Gupta et al., 2019; Bao et al., 2019).

Sequencing is a powerful tool for understanding the diversity of the soil microbiome, but it has some limitations. Extracted DNA comes from both living and dead organisms and so does not indicate which individuals are active in the community. For N_2 fixation, researchers can target the *nifH* gene to determine which NS- N_2 -fixing microorganisms are present, but it does not determine which taxa are actively fixing N. More advanced molecular techniques can help identify the active taxa. Extraction of *nifH* RNA allows identification of organisms that are actively transcribing *nifH* and therefore fixing N (Bahulikar et al., 2014). Stable isotope probing determines which organisms have Fixed-N and subsequently incorporated it into their tissues (Pepe-Ranney et al., 2016). These approaches can be limited though, because they represent a single point in time and are expensive and technically challenging.

Molecular approaches can identify the plant genetic factors that determine rhizosphere NS- N_2 -fixer community composition. For example, multiple genes control rhizosphere N_2 fixation rates in rice (Wu et al., 1995). Within a plant species, cultivars can vary in rhizosphere NS- N_2 -fixer community composition, *nifH* gene abundance, and NS- N_2 fixation rates. Additionally, there is some evidence that older crop varieties and ancestral parents support more NS- N_2 fixation than modern, high-yielding varieties. This cultivar-based variation has been observed in wheat, barley, rice, grasses, maize, millet, and sugarcane, suggesting a plant-based genetic basis for these factors (Roper and Gupta, 2016). With a few exceptions, the specific plant genes responsible for these differences are unknown. Further knowledge of gene-based mechanisms would help in the development of new germplasm (cultivars) with enhanced NS- N_2 fixation potential.

Factors affecting functionality

NS- N_2 fixation is mainly influenced by energy availability along with soil physicochemical properties, environmental and biotic factors, including O_2 availability, soil moisture content, soil texture, nutrient availability, and overlying plant communities (Fig. 4).

The rhizosphere is a C-rich environment conducive to NS- N_2 fixation. It contains root exudates, decomposing soil organic matter, and plant residues, all of which provide C to diazotrophs. Plant roots exude labile C (e.g., sugars), which can be readily used by NS- N_2 -fixing microorganisms. The quality and quantity of that C varies by plant species and life stage, and this may be responsible for observed seasonal variation in NS- N_2 fixation rates. In cereal crops and grasses, rhizosheaths are enriched with organic materials and have a high density of diazotrophs, which support substantial NS- N_2 fixation. Deep and extensive root systems, exemplified in perennial grasses and trees, provide root exudates to a large volume of soil and also provide C via decomposing roots. Surface residue inputs also stimulate NS- N_2 fixation rates in cereal crops (Roper and Gupta, 2016).

NS- N_2 fixation rates are controlled by availability of key nutrients. In general, soil mineral N inhibits NS- N_2 fixation because diazotrophs save energy by taking up soil N. However, when C is abundant, excess mineral N can be immobilized by microbes, lowering mineral N availability and making NS- N_2 fixation energetically favourable. As a result, in some locations, the soil C:N ratio can be a good predictor of NS- N_2 fixation rates, because it indicates the ratio of available energy to the N required for microbial growth. For example, crop residues from cereal crops and grasses can promote NS- N_2 fixation more so than residues with a low C:N ratio, such as those from legumes. In addition, other nutrients such as Mo, Fe, and P are needed for nitrogenase synthesis. As a result, application of P can increase NS- N_2 fixation especially with crops and grasslands in nutrient-poor soils.

The enzyme nitrogenase is denatured by O_2 . In symbiotic N_2 fixation, a special O_2 -transporting protein, leghemoglobin, facilitates a carefully controlled O_2 supply to the N_2 -fixing bacteria. In contrast, NS- N_2 fixation often occurs in microaerophilic or anaerobic microsites in the soil. Some NS- N_2 -fixing microorganisms have evolved strategies for separating O_2 from nitrogenase, and this allows them to fix N_2 in aerobic soils (Puppo and Rigaud, 1986). Nonetheless, NS- N_2 fixation rates generally decrease with O_2 concentration. Similarly, NS- N_2 fixation rates generally increase with soil moisture (Roper and Gupta, 2016), because water-filled pore spaces slow O_2 diffusion and maintain low- O_2 conditions.

Fig. 4 Edaphic and environmental factors influencing the diversity, abundance, and functional capacity of non-symbiotic N_2 fixation.

Other important physicochemical and environmental factors include pH, soil texture, heavy metal concentration, and soil temperature. Nitrogenase activity peaks at pH 7–7.5, and NS- N_2 fixation rates decline at higher or lower pH. The amount and type of clay in soils can alter soil structure and habitat conditions affecting NS- N_2 fixation; for example, the presence of montmorillonite clay increases NS- N_2 fixation rates. Soil contamination by heavy metals reduces the abundance of diazotrophs and rate of NS- N_2 fixation. The most favourable temperatures for NS- N_2 fixation are between 30 °C and 35 °C, but the best temperature range depends upon the diazotroph taxa and habitat conditions; N_2 fixation can occur from near 0 °C to 45 °C.

Soil aggregates are important mediators of biogeochemical processes, such as denitrification and organic C accrual, and they may also influence NS- N_2 fixation rates. Survival of NS- N_2 -fixing bacteria is related to the ability of soil aggregates to protect them against biocides; biocides can reduce the amount and duration of N_2 -fixing activities in soils exposed to adverse environmental conditions. Aggregates formed in the rhizosphere tend to be water-stable and water-stable aggregates can maintain greater soil moisture and lower O_2 concentrations than the surrounding soil (Kuz'yakov and Blagodatskaya, 2015), potentially leading to higher rates of NS- N_2 fixation. Furthermore, aggregates formed in the rhizosphere environment can harbor larger populations of NS- N_2 fixing bacteria. Hence, physicochemical and biological conditions in aggregates likely favour high rates of NS- N_2 fixation.

Plant communities differ in terms of the quantity and quality of plant exudates (i.e. C sources) and signal molecules, which in turn influence both diazotroph community composition and NS- N_2 fixation rates (Fig. 4). For example, perennial grasses with their extensive root systems and large amounts of root derived C generally support more N_2 fixation compared to modern cereal crop varieties. Endophytic diazotrophs gain benefits from living inside the plant, an environment conducive to NS- N_2 fixation because the diazotrophs: (i) have direct access to plant-sourced energy, (ii) can avoid competition from other rhizosphere microbes, and (iii) are in a low- O_2 environment in the plant interior. Because of their location, N fixed by endophytic diazotrophs can be transferred more efficiently to where it is needed in the host.

Future research directions

NS- N_2 fixation remains an area of active research interest. There are several key areas where new research will help us more fully understand NS- N_2 fixation: more reliable annual and seasonal rate estimates, identification of key diazotrophs, and characterization of the underlying ecological relationships. Application of this acquired knowledge to agricultural ecosystems may lead to increased NS- N_2 fixation and improved economic and environmental sustainability.

Accurate crop season and annual estimates of NS- N_2 fixation at a biome and global scale will allow a better understanding of the importance of N_2 fixation in the global N cycle. In addition, the underlying data required to achieve accurate annual estimates will also help inform agricultural management. Most NS- N_2 fixation estimates are based on short-term measurements, conducted under laboratory conditions with samples from a small geographic area. Annual and seasonal scaling is often an extrapolation from these limited samples, which makes biome-scale estimates tenuous. Future experiments may improve scaling by measuring a comprehensive suite of physicochemical predictors and by designing experiments to adequately capture spatial and temporal variability of a given habitat (Soper et al., 2021), an approach that was successfully deployed by Gupta et al. (2006) to derive estimates for different southern Australian agricultural zones. Molecular tools have revealed a wide diversity of N_2 fixing microorganisms across different habitats, but it is usually unclear which taxa are actively fixing N. New molecular techniques, such as mRNA analysis and stable isotope probing, will allow researchers to simultaneously identify the active taxa and their functional capacity at a given time. These tools will help us address key questions, such as: 'do the active taxa vary with physicochemical conditions, geography, or overlying vegetation?' and 'are most *nifH* taxa fixing N or just a few?'

Similarly, the ecological relationship between diazotrophs and plants is unclear. Plants can influence the rhizosphere and root microbiome, including the diazotrophic community and their function. This would require a better understanding of the host-genetic factors regulating diazotroph assembly in roots for identification of key taxa specific to plant type, which could ultimately lead to management changes that stimulate NS- N_2 fixation in cereal crops. As we begin to identify microbial taxa that are actively fixing N, we can tailor investigations to those relevant taxa. In addition, we can apply existing ecological theory on plant-microbe interactions to guide studies of plant-diazotroph interactions. The combination of new molecular tools and existing ecological theory may lead to new insights on NS- N_2 fixation in the near future.

Outlook

As the relationship between active NS- N_2 fixing microorganisms and plants is better understood, we may be able to enhance NS- N_2 fixation in agricultural settings especially in low-fertility soils. Economically affordable and environmentally friendly alternatives to synthetic N fertilizers can improve global food production, particularly in low-income regions. Ideally, we will be able to identify candidate microbes that fix N at higher rates and develop cultivars that select for effective diazotroph populations. Eventually, it could lead to designer plant-diazotroph combinations. One path forward may be the reintroduction of traits from older crop varieties that promote diazotroph colonization into modern varieties to enhance biological N_2 fixation in agricultural systems.

Ideally, development of plant-diazotroph microbe systems in agriculture that behave like the legume—*Rhizobium* symbiosis will lead to improved economic and ecological sustainability for agroecosystems.

Abstract

This chapter describes the biological interactions of the phosphorus cycle. It introduces the mechanism of mineralization and solubilization as well as immobilization of both inorganic and organic soil phosphorus by microorganisms and their dependence on C:P stoichiometry. Along with the importance of the microbial biomass to making P available for plants, the contribution of microbial necromass to soil organic P is crucial. Viruses may be the one of the major drivers of bacterial mortality and necromass-P supply in soil. Further, this chapter discusses the effect of phosphorus solubilizing microorganisms on plant nutrient uptake and describes environmental aspects (specifically, P over-application) of the biological transformations of phosphorus.

Key points

- Soil microorganisms are responsible for organic P mineralization and immobilization of inorganic P into organically-bound forms.
- C:P ratio of the microbial biomass defines the extent to which P is either mineralized or immobilized.
- Both microbial biomass and necromass represent an important part of the organic P pool in soil.
- Phosphorus-solubilizing microorganisms potentially contribute to plant P nutrition and solubilize relatively insoluble inorganic P compounds (e.g. Al-, Fe-, and Ca-phosphates).
- Over-application of both inorganic and organic P-containing materials may result in potential offsite degradation of water quality.

Introduction

Phosphorus (P) is essential to life; it is a primary component of many important biomolecules such as adenosine triphosphate (ATP), nucleic acids (DNA and RNA), phospholipids, phosphopyridine nucleotides (NADP⁺), and phytin (P storage molecule—derivative of inositol hexaphosphate). Plant requirements for P generally account for between 0.2% and 0.4% of plant dry weight. Despite the relatively modest P requirements compared with nitrogen (N), the main challenge with P lies in maintaining enough soluble phosphate to prevent agricultural crops becoming deficient. Taking into account the quick fixation of applied P in the soil and the rapidly depleting stock of phosphate rocks, management of P in agriculture is of major interest (Cordell et al., 2009).

Plant-available phosphate ions, weathered from the primary mineral, apatite, are present in soil in varying concentrations. Phosphorus enters the soil environment through a number of other pathways, for example as anthropogenic P from incinerators that may be transported through the atmosphere and reach soils with precipitation (around 0.02–0.3 kg ha⁻¹ y⁻¹). Phosphorus is applied as inorganic fertilizers, as rock phosphate, or in organic materials such as animal manures, bone meal, seaweed, municipal and other biosolids, as recycled P fertilizers (e.g. struvite-P extracted from wastewaters), or, in undisturbed soil ecosystems, it is simply recycled from plant and animal matter.

Soil native microbial necromass is considered as an important source of labile organic P, becoming plant available after microbial death due to external factors including viral infection. Additionally, significant amounts of P further contribute to the formation of SOM.

The P cycle in soils includes both abiotic and biotic components. The abiotic component is primarily related to the dissolution of P-containing minerals, the formation of phosphates of Al, Fe, Ca, and Mg, and their sorption to clays, Al- and Fe-oxides, sesquioxides and organic compounds in soil. Abiotic and biotic components present the total P pool in the soil, which requires various transformations to become plant-available.

Biological transformations of P in the soil are crucial for recovering both residual inorganic and organic P (as up to 54% of residual P in agricultural soils may be stored in organic form) (Stutter et al., 2012). Microorganisms, nematodes and earthworms effectively increase availability of P in the soil. The biotic components of P cycle primarily involve the mineralization of organic P sources and immobilization of soil solution orthophosphates during microbial metabolism.

Soil microorganisms, including bacteria and fungi living in the bulk soil and the rhizosphere, as well as mycorrhizal fungi, produce a variety of organic acids and chelating agents which facilitate the solubilization of phosphate from the inorganic P and supply P to the plant. The differences among crop varieties in the intensity of residual inorganic and organic P utilization, through the release of phosphatases and organic acids as root exudates, can also be considered as a way to reduce the level of mineral fertilizer application. The capacity of soil to adsorb P is important for understanding the potential stock of residual phosphorus. Mismanagement or over application of P-containing materials can result in excessive amounts of inorganic P, so-called 'legacy P' (Haygarth et al., 2014), which can have both positive agronomic and negative environmental impacts. The 'legacy P' stock, accumulated over past decades, has the great potential to obviate the necessity for further agronomic P inputs. However, although the amount of P stored in soil might be sufficient to satisfy crop requirements to create high yields for many years, without any or with only minimal P input, much of it cannot be taken up by plants because its presence, in forms that are readily available, is limited. For the environment, the entry into surface waters of 'legacy P' and P applied to soil in manure or waste water can result in eutrophication, and further degradation of the quality of the habitat for aquatic organisms.

Forms and sources of soil phosphorus

The original source of most soil P is from the primary mineral apatite, or rock phosphate (RP). Apatite is a highly insoluble Ca-phosphate compound with the general formula of $\text{Ca}_{10}(\text{PO}_4)_6 \times 2$, where X is F^- (fluoroapatite), OH^- (hydroxyapatite), or Cl^- (chloroapatite). In acidic soils, little of these apatite minerals remain in the soil. The P in these minerals is released, either chemically or by biological interactions with microorganisms and plant roots. Over time, available P is taken up by plants or microorganisms and incorporated into organic matter, some is retained in relatively insoluble inorganic P minerals with Al and Fe in acidic soils, and with Ca in neutral to alkaline soils. In highly weathered soils, P is tied up by Al- and Fe-oxides. These compounds are only sparingly soluble (Fig. 1). Generally, solubility of phosphorus from Al and Fe sources increases with pH levels in the range of about pH 5.5–6.5. As the pH rises, however, Ca-phosphate minerals form, which control the concentration of soluble P. Hence, soluble P concentrations decrease significantly as pH increases above neutrality. The low solubility of inorganic soil P makes the use of P fertilizer materials necessary in many high-yielding agricultural systems. The practice of liming acid soils to increase pH to about 6.0–7.0 has the practical effect of enhancing P availability for plant growth.

The total amounts of P in natural soils vary widely, depending on parent material and the extent of weathering. In sandy soils with low organic matter content, there may be $\sim 100 \text{ mg kg}^{-1}$ of total P, while soils high in primary P minerals (e.g., high-phosphate limestone parent materials), clay content, or organic matter may contain well in excess of 2000 mg kg^{-1} soil. In most soils, inorganic P is the dominant form, although organic P increases with increasing soil organic matter. Cultivated soils may accumulate high levels of total P due to regularly P input, especially when large rates are applied.

The plant-available forms of P in soils are orthophosphate ions, H_2PO_4^- (dominant form at pH 2.2–7.2) or HPO_4^{2-} (dominant form at pH 7.2–12.4). Orthophosphate from soluble phosphate fertilizers or mineralized from organic sources rapidly precipitates as Al-, Fe-, or Ca-phosphates or is sorbed by Al- and Fe-oxides and soil organic matter. Due to these reactions, soluble P is present at very low concentrations in soil solution, typically in the range of less than $0.1\text{--}1 \text{ mg L}^{-1}$. In unfertilized soils the solution orthophosphates must be continuously replenished by chemical or biological dissolution of inorganic P compounds or by microbial mineralization of organic P.

Organic P commonly accounts for 30–50% of the total soil P in most soils, but it can vary from 3% to 90%. The P content of soil organic matter (SOM) ranges from about 1 to over 3%. Total organic P in a soil is a function of organic matter content, so that as organic matter increases, so does organic P. Organic P also decreases with soil depth, as does organic C.

The major types of organic P compounds, which are added to soil by recycling plant, animal, and microbial remains in the soil, are shown in Fig. 2. Under aerobic conditions, phytins or inositol phosphates, are usually found in the greatest quantities, making up to 40% of the total organic P content. The inositol phosphates are typically in a polymeric state, making these compounds relatively resistant to decomposition. Other organic P compounds include more labile phosphomonoesters (up to 43% of all organic P) and phosphodiester, such as DNA and RNA (making up 17%) (Darch et al., 2014; Spohn, 2020). Remaining forms of organic P, including phosphonates and organic polyphosphates, are present in trace amounts only and differ markedly in their bioavailability and transformation pathways in the soil.

Since inorganic forms of P are quite rapidly and strongly bound to or within secondary minerals, their availability to plants and leaching from soil are essentially restricted. Dissolved organic P forms can be more mobile within the soil, compared to inorganic P, due to weaker sorptive retention.

Fig. 1 Solubility of orthophosphate from variscite ($\text{AlPO}_4 \cdot 2\text{H}_2\text{O}$), strengite ($\text{FePO}_4 \cdot 2\text{H}_2\text{O}$), and various Ca-phosphates as a function of solution pH. These equilibria assume a Ca^{2+} concentration of $10^{-2.5} \text{ mol L}^{-1}$ and CO_2 at 0.03 kpa. Organic P compounds sorb strongly to positively charged mineral surfaces (e.g. amorphous Al and Fe oxides and the facets of clay minerals). This protects organic compounds against decomposition because sorption physically hinders enzymatic catalysis. As a result, organic P compounds may contribute to the sorptive stabilization of SOM against microbial decomposition in soil (Kleber et al., 2007).

The microbial biomass represents an important part of the organic P pool in soil. This pool represents actively cycling P in the soil, and is a part of the labile or readily available organic P. Microbial activity is responsible for mineralization and immobilization reactions that convert organic P into inorganic P and inorganic P into organically bound P. The microorganisms are also able to solubilize the relatively insoluble Al-, Fe-, and Ca-phosphates. In arable soils the biomass-P fraction accounts for up to 5% of the total organic P pool, while in undisturbed grassland and forest soils, the fraction may be as high as 40% (Turner et al., 2013). Soil disturbance, e.g., tillage, reduces organic matter and total organic P content, and in general the microbial biomass P fraction decreases more rapidly than the total organic P pool. Therefore, the labile organic P fraction is more susceptible to disturbance than the more stable, complex organic P forms. This indicates the importance of the microbial biomass to making P available for plant use in stable terrestrial ecosystems.

Microbial necromass as a source of labile organic P

In recent years there has been increasing evidence of a large contribution from microbial necromass to both SOM and soil organic P. Microbial necromass accumulation is an important way of sequestering C, making up as much as 30–60% of the topsoil SOM (Liang et al., 2019). By degrading plant-derived organic compounds to grow and reproduce, microorganisms immobilize P and it is stabilized as necromass in soil. Further transformations of this necromass include its mineralization and involvement in its turnover or stabilization (by aggregation and bonding to the mineral matrix of the soil).

As a source of available C and N, microbial necromass influences microbial P utilization. The global ratio of C:N:P for microbes is 60:7:1 (Cleveland and Liptzin, 2007). Such a narrow ratio compared to other sources of soil P makes microbial necromass an ideal source of nutrients, especially under P deficiency.

Fig. 2 Organic phosphorus forms with generic and example structures, information on the lability and prevalence (George et al., 2018).

Microbial processes in the soil that promote soil C turnover depend on the intensity of land use. It is suggested that the turnover of living microbial biomass is faster in croplands and grasslands compared with forest soils, and the contribution of fungal derived necromass C to SOM is consistently greater than bacterial necromass C in all soils (approx. 65–35%, respectively, with a higher ratio of fungal:bacterial necromass C for forest soils) as fungal necromass is preferentially protected in the soil and involved in the formation and stabilization of soil aggregates. At the same time, microbial biomass is preferentially utilized by bacteria, whereas fungi, especially ectomycorrhizal, are better adapted to utilize plant litter (López-Mondéjar et al., 2020).

Soil fauna and viruses are also involved in microbially-mediated C transformation processes and consequently influence microbial necromass production, recycling and SOC dynamics. Bacterial death is generally caused by external factors. Viruses

Fig. 3 Changes in carbon (C), nitrogen (N) and phosphorus (P) stoichiometry in initial bacterial host, viruses, and remaining bacterial lysates after viral lysis (relative to the initial content in bacterial host cells). The upper numbers (in black) show the C:N:P ratio of each component, the lower numbers (in blue) represent normalized data to the total amount of each element in the bacterial host (C:N:P = 1:1:1) (Kuzakov and Mason-Jones, 2018).

(i.e., bacteriophages) may be one of the major drivers of bacterial mortality in soil. Considering very high infection rates for bacteria and the short time to lysis, the average lifetime of bacteria in soil may be weeks, at most. It is suggested that viruses induce bacteria turnover in soil. Viral infection turns over the microbial population by cell lysis, thus releasing immobilized nutrients including P for root uptake (Kuzakov and Mason-Jones, 2018).

Unlike C and N, where the ratio in soluble cell lysates is very close to that of whole cells, host P is incorporated into nucleic acids of new virions, thus increasing the C:P ratio of the lysate and leading to a microscale divergence of C:N:P ratio in bacterial lysates after viral lysis (Fig. 3).

Higher P enrichment of viruses, compared with C and N, may lead to a strong depletion of P in the remaining lysates and it becoming temporarily inaccessible. However, although these concepts still need experimental verification, they are reasonable to consider in assessing P transformations in the soil.

The phosphorus cycle

The dynamics of P in the soil is governed by an interaction of chemical, physical and biological factors, which in turn are affected by environmental conditions and land use (Fig. 4). In some ways, the phosphorus cycle is not as complex as the nitrogen and sulfur cycles, because P typically does not undergo oxidation–reduction reactions or exist in gaseous forms. However, as for the N and S cycles, the biological processes of mineralization and immobilization as well as plant uptake are present. Additionally, the microbial fraction is active in the solubilization of relatively insoluble inorganic P materials, making P available for plant or microbial uptake or other transformations.

In the biological subcycle, soluble orthophosphates are either taken up by plants or immobilized into the microbial biomass. When organic sources of P, such as crop residues, manures and municipal biosolids, are land-applied, P may suffer three distinct fates. Organic forms, especially inositol phosphates, may be incorporated directly into stable SOM, becoming relatively unavailable for plant and microbial use. If the material has a relatively large P content relative to C and N, a portion of it will be mineralized to orthophosphate during microbial decomposition. Finally, part of the P will be incorporated into the microbial biomass (immobilized) during decomposition. This immobilized P may become available as soluble P when the microbial biomass fraction dies (e.g. forming a necromass) and is itself mineralized by other microorganisms, as described above.

Although this model of the P cycle segregates biological activity from geochemical activity, it should be noted that the dissolution of apatite and other secondary P minerals can be enhanced by the activities of microorganisms and plants. Dissolution or solubilization of these minerals releases P as orthophosphate into solution, where it can then be utilized by plants or microorganisms. Essential portions of this P will again precipitate as secondary P minerals or be adsorbed onto Al- and Fe-oxides or clay surfaces.

Fig. 4 The phosphorus cycle showing inputs, losses, and transformations. This model illustrates the relationship of the chemical and biological P subcycles through the solution orthophosphate pool. Adapted with permission from Walbridge MR (1991) Phosphorus availability in acid organic soils of the lower North Carolina coastal plain. *Ecology* 72: 2083–2100.

Mineralization and immobilization of P

As briefly discussed above, key components of the biological cycling of P in soil are mineralization (the transformation of organic P into inorganic orthophosphate P), and immobilization (the transformation of inorganic P back into organic forms). These reactions are catalyzed by those microorganisms that are active in the soil, and are largely the consequence of heterotrophic microbial catabolic and anabolic processes. To acquire energy, electron-rich organic compounds are oxidized and degraded to produce energy. As these compounds are decomposed, inorganic nutrients are released. To build new cells, the biomass must acquire inorganic P and other nutrients. The extent to which P is either mineralized or immobilized during these reactions depends on the C:P ratio of the substrate being degraded. If the C:P ratio is 200:1 or less, then the residue is rich in P and the excess will be mineralized. Conversely, if the C:P of the residue is greater than about 300:1 there will not be enough P available in the residue to facilitate complete degradation. Therefore, immobilization of orthophosphate from the soil into microbial biomass will occur if decomposition of the residue and biomass growth is to continue (Bilyera et al., 2021).

Although immobilization decreases the amount of orthophosphate immediately available to plants, it is typically a very short-lived phenomenon and may protect orthophosphate from being tied up in relatively insoluble inorganic compounds. After organic amendments are mineralized, the microbial biomass will begin to die back to previous levels, resulting in the subsequent mineralization of the microbial P pool.

Mineralization is simply the enzymatic release of orthophosphate or another organic P intermediates (i.e., diesters → monoesters → orthophosphate), during the decomposition of organic materials that contain P. The phosphatase enzyme group is extracellular and responsible for the hydrolysis of esters and anhydrides of orthophosphate-P. A number of different phosphatase enzymes are observed in the soil environment. The most commonly measured soil phosphatases are the phosphomonoesterases, which hydrolyze phosphomonoester bonds. Two phosphomonoesterases have been widely studied: acid phosphatase and alkaline phosphatase. Acid phosphatase is produced by microorganisms and plants and predominates in acid soils, while alkaline phosphatase is only produced by soil microorganisms and is dominant in alkaline soils (although it is present in acid soils as well). Phytase is also an important enzyme as phytate (i.e., inositol phosphates, Fig. 3) can make up as much as 40% of the organic P in a soil. Therefore, phytate hydrolysis can be an important source of orthophosphate, supporting plant nutrition. These extracellular enzymes, actively excreted into soils by organisms, can also accumulate in soil, protected by sorption to organo-clay complexes in the soil. These enzymes are important, not only for the degradation of freshly added organic residues, but also for the release of inorganic P from soil organic matter. Activity of phosphatases (phosphomonoesterase) is generally inhibited in plant roots and rhizosphere soil after application of inorganic P and stimulated under P deficient conditions or at organic P application (Janes-Bassett et al., 2022).

Microbial solubilization of inorganic P

Microorganisms are also important in the solubilization of P from mineral sources. Orthophosphate is typically present in soil solution at very low concentrations. This solution P is replenished either from mineralization of organic P sources, as discussed above, or from the dissolution of P from phosphate minerals, which in soils is primarily apatite. In acidic soils, secondary inorganic P minerals in the form of aluminum and iron phosphates, such as variscite ($\text{AlPO}_4 \cdot 2\text{H}_2\text{O}$) and strengite ($\text{FePO}_4 \cdot 2\text{H}_2\text{O}$), dominate. In alkaline soils, it is calcium phosphates that dominate (e.g., $\text{Ca}_3(\text{PO}_4)_2$).

Most forms of inorganic P in soil have limited solubility. It is generally agreed that microorganisms can facilitate the enhanced dissolution of these compounds by at least two mechanisms: production of organic acids and excretion of protons during NH_4^+ assimilation, resulting in chelation of cations or reduction in pH to release P. These mechanisms are performed by soil fungi and bacteria and appear to be potentially important, especially in soils receiving little or no phosphatic fertilizer materials.

Phosphate solubilization has been observed in many different species of bacteria, including actinomycetes, fungi, and algae, collectively labeled as Phosphorus Solubilizing Microorganisms (PSM). Bacterial species reported include those in the genera *Bacillus*, *Pseudomonas*, *Agrobacterium* and *Micrococcus*, *Nitrosomonas*, and others. The most commonly reported P-solubilizing fungi are *Aspergillus*, *Azospirillum* and *Penicillium* species, although a number of other species have been reported to solubilize P. In soil, P-solubilization activities are greatest in the rhizosphere. The plant root system provides ample quantities of readily utilized carbon, which results in high microbial activity. The activity of P-solubilizing organisms in the rhizosphere can be potentially important for the P nutrition of plants. In general, it appears that fungi may be more important to the solubilization of inorganic phosphate in soil than bacteria. Fungal hyphae can grow across distance in soil microenvironments, allowing for exploitation of P resources not available to relatively immobile bacteria. However, according to so-called 'biological markets' the amount of P provided by fungus depends on the amount of C received from a partner plant (van't Padje et al., 2021).

Organic acids produced by bacteria and fungi have been shown to solubilize various forms of inorganic phosphates (Alori et al., 2017). Citric, and other organic acids, can be quite effective in solubilizing largely insoluble forms of P, such as AlPO_4 . The efficacy of organic acids as P-solubilizing agents in liquid media is due to their effect in lowering the pH, which facilitates acid hydrolysis of AlPO_4 , and the released Al^{3+} . The latter is then complexed with the organic anion. This chelation or complexation of the released Al helps to minimize re-precipitation of Al-phosphates and the potential for Al-toxicity on acid soils. While organic acids appear to be effective in solubilizing Al-phosphates, solubilization is typically more effective in the presence of microbial cells than that observed with organic acids alone. In addition, some organisms solubilize Al-phosphates with no appreciable production of organic acids. Proton accumulation during the assimilation of NH_4^+ or due to respiratory activities appears to be a primary mechanism in the absence of organic acids (Alori et al., 2017).

Dissolution of Ca-phosphates, such as rock phosphate or $\text{Ca}_3(\text{PO}_4)_2$, also occurs due to organic acid production or the accumulation of protons during ammonium assimilation or respiration. Typically, a decrease in the pH of the growth substrate occurs during solubilization of P from these minerals. The pH decrease is most pronounced, and solubilization is usually highest, in the presence of ammonium N sources. While organic acids can be effective in solubilization of Ca-phosphates, they are not always produced by all organisms capable of the process.

P-solubilizing microorganisms and plant growth

Inoculation of crops with PSM has produced controversial results. In the 1950s in the former Soviet Union, researchers reported excellent results when spores of *Bacillus megatherium* var. *phosphaticum* (also referred to as phosphobacterin) were applied to soils that were neutral to alkaline in pH and with a high organic matter content. The mode of action was thought to be the mineralization of organic P. Subsequent research, mainly in the United States, was not able to verify the claims of significant crop yields and the practice has never been adopted. Recently, the pH decrease has been reported as the most probable mechanism. Phosphorus solubilizing bacteria are acidifying microorganisms, which mobilize Ca bounded phosphate via proton secretion. Other mechanisms of P solubilization include the production of organic anions, which can either complex P by ligand-promoted mechanisms, or they can directly desorb orthophosphate P from soil minerals. The production of a wide range of phosphatase enzymes by microorganisms can also mobilize orthophosphate from organic P forms in soil.

The effects of PSM are variable under controlled and field conditions. Under controlled conditions, inoculations with PSM improved plant growth and P shoot content, especially on low P soils. In some studies under field conditions, there was little or no effect, whereas other research has shown positive effects of inoculation on plant yields and P uptake. The effectiveness of PSM decrease under regions of increased temperatures and smaller precipitation. Another reason for the lack of field PSM performance on crop productivity and P uptake may be related to poor soil colonization due to competition with other native microbial communities. Expectedly, soil pH is also important for the efficacy of PSM to solubilize soil P. Generally, inoculation is more effective at higher soil pH (i.e. calcareous soils), where acidification is considered to be the main cause of increased P availability.

Availability of P in soil is also regarded as a necessary requirement for PSM performance. To achieve positive plant response to PSM, some threshold P availability should be met. A meta-analysis revealed that inoculation resulted in a greater yield increase under conditions with moderate P availability in soil, but was less effective in more P-deficient environments (Schütz et al., 2018).

Fig. 5 Overview of the two conceptual pathways for phosphate-solubilizing microorganism(s) (PSM). Scenario A represents the ideal PSM contribution to plant P nutrition in which excess P is solubilized in soil to meet plant needs considering adequate nutrient supply (i.e. carbon and nitrogen). Scenario B illustrates PSM solubilizing P to sustain their own need and serve the system over the long term by releasing P from their biomass turnover (Raymond et al., 2020).

Ideally, microorganisms contribute directly to plant P nutrition solubilizing P from soil to meet plant needs, as shown in Scenario A (Fig. 5). Another possible pathway (Scenario B, Fig. 5) is to facilitate microbial biomass turnover to serve over a long term (Raymond et al., 2020). Microbial P mobilization may be enhanced by a general decrease in microbial biomass, which depends on C and N availability and their ratio in soils. In a P-rich environment, soil microorganisms will use available P, whereas in a P-limited environment it will drive P-solubilization activity within the microbial biomass.

Although, other factors than the putative P availability alone may contribute to field performance of PSM. Among them are stimulating effects on plant growth and biological nitrogen fixation, and availability of other essential nutrients (e.g., Zn and Fe).

Phosphorus and the environment

Concern over the impact of P on the environment has re-emerged over the past decade. Over application of P-containing materials, whether inorganic fertilizers or organic amendments, can result in high levels of extractable soil inorganic phosphate. If these soils are close to surface waters, then this P can be exported to those waters either as soluble P in runoff water or as P adsorbed to eroded soil particles. In both cases, this can result in the increase of bioavailable P in these waters. This, in turn, can potentially lead to eutrophication, which occurs when excess nutrients, typically N or P, accumulate in the water, resulting in accelerated growth of algae. These algae can cloud the water, decreasing light penetration, resulting in decreased growth of aquatic plants. Increased algal biomass production stimulates higher rates of degradation in the water column by bacteria. This accelerated decomposition then decreases available oxygen, often making the habitat unfit for many forms of aquatic life.

Many soils that have received regular applications of manure over time have accumulated large values of total and available P. If manure is applied to a crop to satisfy N requirements, too much P is typically applied, resulting in a P buildup. Although much of the P in these solid manures is added in the organic form, the result is typically a significant increase in the total amount of inorganic phosphate due to hydrolysis by phosphatase enzymes in both soil and water. The last fact highlights the importance of organic P for eutrophication and the necessity to focus on organic P in addition to inorganic when considering P transfer from agricultural lands.

Microbial mineralization of manure releases the phosphate ion, with a significant proportion remaining relatively labile. This lability may be due to the concomitant increase in soluble soil C that may then competitively bind to P-sorption sites or with soil Al and Ca, reducing P complexation potential. Microbial mineralization of these organic P sources over long periods can therefore result in potential degradation of the quality of nearby water bodies.

Modern environmental initiatives to decrease the CO₂ concentration in the atmosphere, by promoting land management practices that sequester organic C in soils, have received both approval and criticism. One of the concerns is simultaneous sequestration of organic P along with carbon, especially in mineral soils. More P input will be needed to sequester C and such co-sequestered P will be stored in soil, but not available to plants, if SOM management aims to keep increased SOM levels (Spohn, 2020).

Summary

Despite of relatively modest P requirements, phosphorus deficiency remains the second largest concern for the world agriculture after nitrogen. Considering the depletion of mined phosphate rocks and the quick fixation of applied P in soil, understanding P mineralization and immobilization by soil microorganisms is essential. Mineralization occurs if the C:P ratio is 200:1 or less, when the residue is rich in P. Mineralization is simply the enzymatic release of orthophosphate or another organic P intermediates. At C: P > 300:1 there will not be enough P available in the residue to facilitate complete degradation and immobilization occurs. Furthermore, viruses are one of the major drivers of mortality among bacteria in soil. As viral infection drives cell lysis this accelerates the turnover of the microbial biomass, in the course of which immobilized nutrients including P may be released and made available for uptake by plants. Microbial necromass consisting of the residual mixtures of intracellular and extracellular biomolecules may be an important source of labile organic phosphorus. The global ratio of C:N:P for microbes (60:7:1) is narrow compared to other sources of soil P making microbial necromass an ideal source of nutrients, especially under P deficiency. Phosphorus solubilizing microorganisms might, under the right conditions, facilitate P nutrition and thus enhance plant growth. Normally, P solubilization occurs mainly in the rhizosphere, which is both a microbial hotspot and a zone for P uptake. The release of organic acids produced by bacteria and fungi, as well as decrease in pH are the most probable mechanisms to solubilize various forms of inorganic phosphates. Over application of both inorganic and organic P-containing materials may result in potential offsite degradation of water quality. Environmental initiatives like C sequestration may lead to co-sequestered P in soil, which causes increased requirements for P input.

Abstract

The element sulfur (S) plays an essential role in the development and proper cellular functions of all organisms. Biological S transformations are key processes to provide available S for organisms. These transformations consist of multiple pathways such as oxidation, reduction, assimilation, and mineralization of various sulfur compounds by microorganisms. This chapter summarizes the current knowledge about the main pathways of the biological S transformations in the soil. The significance of oxidation, reduction, assimilation, and mineralization of S is discussed in relation to soil characteristics and environmental factors in terrestrial and aquatic ecosystems.

Key points

- Sulfur cycling is driven by the processes of oxidation, reduction, assimilation, and mineralization.
- Microbial cell- and extracellular enzymatic reactions catalyze sulfur mineralization from organic matter.
- Assimilation converts inorganic sulfur into organic sulfur.
- Some microorganisms gain energy from sulfur oxidation.
- Organisms perform sulfur disproportion by using sulfur as electron donor and acceptor.
- Assimilation and dissimilation trigger sulfur reduction coupled with the oxidation of hydrogen or organic compounds.

Introduction

In soil, sulfur (S) exists in a variety of forms, some of which are beneficial to the environment, and other forms that are typically considered pollutants. The wide array of oxidation states and forms of S results in a rich diversity of biological transformations involving this important element. These transformations are critical for many basic ecological processes such as plant growth, but also influence the movement of environmental contaminants.

The biological transformations of S can be divided into four major classes: (1) oxidation; (2) reduction; (3) assimilation; and (4) mineralization (Fig. 1). In addition, microbial metabolites can chemically fix or solubilize inorganic S compounds. The first two classes are related to the acquisition of energy for growth and the last two are typically related to nutrient acquisition. For energy acquisition, S can act as an electron acceptor, an electron donor, and sometimes both at the same time. The sulfate anion (SO_4^{2-}) acts as an electron acceptor and is reduced to S^{2-} by a group of bacteria known as sulfate-reducing bacteria. These bacteria grow in the absence of oxygen. In contrast, S^{2-} can act as an electron donor and is oxidized by a group of bacteria known as S oxidizers. These bacteria grow in the presence of oxygen. Interestingly, some bacteria can disproportionate S, i.e. intermediate-valence S species are simultaneously reduced and oxidized to form different products. In this reaction, one of the two S atoms, present in thiosulfate as S^{1-} , acts as an electron donor and the other S atom, present as S^{5+} , acts as an electron acceptor.

Fig. 1 The biological transformations of sulfur (S). Four main processes (oxidation, reduction, assimilation, mineralization) are shown. S_{org} : organic S forms, S_{min} : mineral S forms. Oxidized and reduced states of S correspond to both forms of S.

The last two classes of S transformation are directly linked to the nutritional status of the cell. Mineralization is a transformation in which organic S contained in a growth substrate is released by the cell in a mineral form such as sulfate. In contrast, assimilation is a process in which S present in the environment is incorporated into biomass. In the former case, the mineralized S is available for other organisms to use, whereas in the latter the assimilated S is no longer available to other organisms. Each of these transformations of S has important side-effects on the environment. The mineralization of S provides sulfate, which can potentially stimulate sulfate-reducing bacteria that play important roles in the arsenic and mercury biogeochemical cycles. The oxidation of reduced S by S oxidizers results in acid mine drainage, one of the primary detrimental impacts of mining.

The global sulfur cycle

The global cycle of S begins with S volatilized largely as dimethylsulfide from marine algae, marshlands, mud flats, plants, and soil entering the atmosphere. This dimethylsulfide is converted photo-chemically to methanesulfonic acid, which then deposits on to the Earth and is rapidly converted by bacteria to carbon dioxide and sulfate. This sulfate is assimilated by plants and immobilized into compounds like sulfoquinovosyl diacylglycerol, or alternatively the S is released back to the atmosphere as dimethylsulfide. As plants die, bacteria metabolize the S present in plant biomass and either immobilize this S into their biomass or release it as sulfate for uptake by plants. In addition to this natural S cycle, human activities have at least doubled the input of S to terrestrial systems. Approximately 1.5×10^{11} kg S per year is deposited due to atmospheric pollution, largely in the form of sulfuric acid (sulfate), with small amounts of sulfite and bisulfite also being deposited. This deposited sulfate can either be used by bacteria as a terminal electron acceptor or assimilated by organisms requiring S as a nutrient. Despite this recent disruption of the global S cycle, the S levels present in soil are largely due to pedogenic factors like climate, vegetation, and parent material. As a result, S levels in soil range from 0.002 to 10%: most of this S, 90%, is found in organic form.

The biological availability of sulfur

Although 90% of S in soil is present as organic S, much of this organic S is not available for assimilation or dissimilation by microorganisms and plants. Microorganisms need to convert the organic S in soil into sulfate before plants can take up the sulfate as a nutrient. This conversion of sulfate from organic S is the end result of a complicated biogeochemical cycle. Sulfur enters the soil typically with the residues of plants and animals and is converted and assimilated by microorganisms into their biomass. Predators then consume the prey bacteria and excess S is released into the soil solution. The S released into the soil solution is available for uptake by other organisms or plants. However, the predators do not mineralize all the S present in prey organisms and, as a result, a small fraction of S enters what is termed the 'resistant' pool of organic S present in soil (Fig. 2). This resistant pool of organic S is found as large polymers that are in close association with clays. These large polymers resist microbial attack, either because they are physically protected or because it is not energetically favorable for microbes to attack these polymers. There are three distinct pools of S in soil: (1) inorganic sulfate that is readily taken up by plants and microbes alike; (2) short-lived organic S compounds like taurine, cysteine, cystine, and methionine which are mineralized by microorganisms and either released as sulfate or incorporated into biomass; and (3) long-lived, resistant organic-S polymers found in soil humus can be stabilized through associations with soil clays. Microbial transformations are the primary process by which S is transferred between the pools of readily available and recalcitrant organic S. These transformations are discussed below.

Mineralization

Almost exclusively, microorganisms mediate S mineralization. By definition, mineralization is the metabolic conversion of an organic form of an element to an inorganic form. Mineralization processes can be divided into cell-mediated or extracellular enzymatic processes. Cell-mediated mineralization occurs by oxidative decomposition under aerobic conditions or by desulfurization under anaerobic conditions. In cell-mediated mineralization, S present in carbon-containing compounds is mineralized as organisms consume the carbon. Thus, if there is more S in the substrate than organism requires, the S will be mineralized and released to the environment. If there is not enough S, then any released S is consumed and immobilized by the organism. The

Fig. 2 Different sulfur (S) pools present in soil and their relationship to plant-available S. Size of circles reflects the relative size of respective S pools. Color of circles shows a relative turnover of S pools from fast (yellow) to slow (brown). Arrows and their sizes demonstrate the direction and intensity of S fluxes between pools, respectively.

break-even point for mineralization can be calculated based on the C:S ratio of the substrate, the C:S ratio of the organism, and the yield coefficient, i.e., how much of the consumed C is incorporated into biomass. As a general rule of thumb, if the C:S ratio of a substrate is 200 or less, then S is released. If the C:S ratio is greater than 400, then S is not going to be released because the microorganisms require the S for their own metabolism. In this latter case, organisms rely on a second, enzymatic method of mineralization to obtain the S essential for growth.

Enzymatic mineralization involves extracellular enzymes, such as arylsulfatases, released by the microorganism. These enzymes, once released from cells, will hydrolyze sulfate esters present in the soil. This process releases sulfate into the soil solution for use by the cells. The activity of these enzymes depends on a wide range of soil factors with reaction rates varying by a factor of 4 between different soils. These enzymes attack the vast amount of S present in the soil as organically bound S. Organic S in soil constitutes more than 90% of the total S present in soils. This organic S can be grouped into carbon-bonded S and organic sulfates. Organic sulfates, which comprise between 30 and 75% of S in soil, typically include compounds such as sulfate esters (C—O—S), sulfamates (C—N—S), and sulfated thioglycosides (N—O—S)- the forms of sulfate that enzymatic mineralization processes attack.

Mineralization processes are biological transformations of S that are intimately linked to cellular growth. Thus, factors that influence microbial activity, such as moisture, temperature, or plant growth, will influence mineralization. Increasing the growth of microorganisms by either adding a carbon source or plant growth typically results in reduced mineralization.

Assimilation

Assimilation is the process of converting inorganic S into organic S present in an organism. This assimilatory process is intimately linked to mineralization. In fact, the two processes, assimilation and mineralization, occur simultaneously. If the net effect is to release inorganic sulfate then this is termed mineralization; if instead the net effect is for the S to be incorporated into the biomass, then this is termed assimilation. Thus, the first step of many assimilation processes is the conversion of S into a form that can be incorporated into biomass. Taken alone, such steps might be considered as mineralization processes but we term them assimilatory processes if: (1) the sum of the steps is to incorporate S into biomass and (2) they are induced by S limitation, suggesting that the organism is using the process to obtain S. There are different biological assimilatory transformations that can occur depending on what form the available S is in. The assimilation of sulfate can be summarized in four steps (Droux, 2004): (1) uptake of sulfate; (2) activation of sulfate; (3) reduction of sulfate; (4) synthesis of L-cysteine (Cys). For inorganic SO_4^{2-} , an enzyme called adenosine triphosphate (ATP) sulfurylase mediates the reaction between sulfate and ATP and sulfate to form adenosine-5'-phosphosulfate (APS) (Fig. 3, top side). In turn, this APS is transformed by APS kinase with another ATP molecule to form adenosine-3'-phosphate-5'-phosphosulfate (PAPS). This high-energy molecule reacts with PAPS reductase and two sulphydryl groups to form sulfite, and sulfite is reduced by NADPH_2 to form sulfide which is incorporated into L-cysteine by O-acetylserine sulphydrylase. This pathway will efficiently scavenge excess sulfate present in the soil solution that organisms require. So much so, that in the presence of an energy source, S added as SO_4^{2-} is quickly incorporated into the organic fraction of the soil biomass and later found in the fulvic acid fractions. However, sulfate is not commonly found in soil solution and organisms have developed other pathways to assimilate S for their metabolic needs.

Fig. 3 Metabolic pathways of assimilation (top side) and dissimilation (bottom side) of inorganic sulfur (S). Abbreviations: ATP, adenosine triphosphate; APS, adenosine-5'-phosphosulfate; PAPS, 3'-phosphoadenosine-5'-phosphosulfate; Sat, ATP sulfurylase; Apk, APS kinase; Ppr, PAPS reductase; Sir, sulfite reductase; Apr, adenylyl-sulfate reductase; Dsr, dissimilatory (bi)sulfite reductase.

Aromatic sulfonates, SO_3^{1-} groups bound to aromatic rings, can also serve as a S source for assimilation. This assimilatory pathway is controlled by a genetic cluster called the 'sulfate-stimulation-induced stimulon' that encodes three distinct gene clusters, *asf*, *ssu*, and *ats*. Together these three genes control the assimilation of S by bacteria in soil. The *ats* gene cluster is responsible for the binding of aromatic sulfonates and transportation into the cell. The *ssu* genes encode for the cleavage for the C—S bond by a monooxygenase. The *asf* gene cluster provides the reducing equivalents from the oxidation of NADH necessary to assimilate aromatic sulfonates. The overall result of this pathway is the production of sulfite, which reacts with PAPS reductase to form sulfide, as described above. Alkane sulfonates are also a source of S for assimilation. For most alkane sulfonates the pathway is very similar to that described above, with the exception that the transport mechanisms differ. There is a distinctly different pathway for taurine, involving an α -ketoglutarate-dependent dioxygenase which oxidizes both taurine and α -ketoglutarate to release sulfite. This pathway is regulated by *TauD* and is specific for taurine, with little activity seen for other alkane sulfonates.

Sulfate esters are assimilated by the action of three separate enzyme families (Linder, 2018), including arylsulfatases, metallo- β -lactamase (MBL)-like sulfatases, and α -ketoglutarate/Fe(II)-dependent dioxygenases. Arylsulfatases are broadly grouped by their pH optima, with alkaline sulfatases having a pH optimum of 8.3–9.0 and acid sulfatases having a pH optimum of 6.5–7.1. In essence, arylsulfatases hydrate the S—O bond and release sulfate (Fig. 4; top reaction), which can then be assimilated by the pathway described above for sulfate. These assimilatory processes should be clearly differentiated from processes that use organo-sulfur compounds as a C and energy source. Organo-sulfur assimilation genes are regulated by the sulfate-stimulation-induced stimulon, which in turn is regulated by levels of cysteine, thiosulfate, and sulfite present in the cell. The presence of these

Fig. 4 Reaction mechanisms for desulfurization of sulfate esters. Metal ion requirements for each enzyme family are indicated.

compounds inside the cell will downregulate the sulfate-stimulated-induced genes and thereby repress expression of assimilatory enzymes. This is a logical regulatory control, since if there is an excess of cysteine and sulfate present in the cell, the cell likely does not need to assimilate S. The MBL-like sulfatases are involved in aliphatic sulfate ester desulfurization and produce sulfate and the corresponding aliphatic alcohol (Waddell et al., 2017) (Fig. 4; middle reaction). Unlike arylsulfatases, the MBL-like sulfatases hydrate the C—O bond. The α -ketoglutarate- and Fe(II)-dependent dioxygenases utilize sulfate esters and α -ketodicarboxylic acids as co-substrates. The α -ketoglutarate- and Fe(II)-dependent dioxygenases hydrate the C—O bond with the help of one oxygen atom derived from molecular oxygen and produce sulfate and aliphatic aldehyde (Fig. 3; bottom reaction). Meanwhile, the α -ketodicarboxylic acids are oxidatively decarboxylated into succinate.

Sulfur oxidation

Many organisms, such as chemoautotrophs and photoautotrophs, use S as a source of energy. This occurs by oxidizing S^0 to SO_3^{2-} and finally to SO_4^{2-} and in the process stripping six electrons from S and using oxygen or nitrate as a terminal electron acceptor. A great variety of thiobacilli can perform these reactions. Some thiobacilli are chemoautotrophs (only able to use S as an energy source), others are facultative chemoautotrophs (able to use C as an energy source if necessary) and some are mixotrophs (able to use C and S as an energy source at the same time). Most thiobacilli require the presence of oxygen but some, such as *Thiobacillus denitrificans*, can use nitrate as a terminal electron acceptor. Similarly, some thiobacilli can use Fe^0 in addition to S as an electron donor.

The research on the importance of thiobacilli on S oxidation comes largely from pure culture studies. The actual situation in soil involves a wide diversity of organisms. There are gliding S oxidizers, including bacteria, the cells of which are arranged in trichomes, which show a gliding motion on the substrate. The most important members of this group in relation to S-oxidation in soils are species of *Beggiatoa*, bacteria that participate in sulfide oxidation in the root zone of rice. All strains of *Beggiatoa* deposit S in the presence of H_2S :

Phototrophic bacteria, such as *Chromatium* and *Chlorobium*, also play an important role in sulfide oxidation in rice paddy soil, but not in aerobic agricultural soils. A number of nonfilamentous, chemolithotrophic sulfur-oxidizing bacteria, such as *Sulfolobus*, *Thiospira*, or *Thiomicrospira*, have also been isolated from special habitats, but the importance of these bacteria in S oxidation in soils has yet to be determined. Some thiobacilli, such as *Thiobacillus denitrificans*, can oxidize S or thiosulfate and use nitrate as an electron acceptor. Other aerobic bacteria, such as *Arthobacter*, *Bacillus*, and *Pseudomonas*, oxidize S in soil during their normal metabolism of oxidizing organic compounds in soil and using oxygen as a terminal electron acceptor. These reactions have not been characterized but it is thought that this is occurring as a side reaction to the primary transformations being carried out by these organisms. In the soil ecosystem, it is widely assumed that thiobacilli are the dominant S oxidizers but this view is based on the observation that if you add elemental S to soil, the numbers of thiobacilli increase. However, no consistent correlation between S-oxidation rates and the prevalence of thiobacilli has been demonstrated, except in very broad terms. In general, it is assumed that initially heterotrophs oxidize elemental S until the pH is low enough that oxidation of S by chemoautotrophs is energetically favorable and then thiobacilli dominate. Thus, under energy-limiting conditions in an environment dominated by dissolved, reduced S compounds with little organic matter, thiobacilli will dominate. In contrast, in a soil in which there are significant amounts of organic matter and less reduced S, heterotrophs will dominate.

Microorganisms responsible for S oxidation are generally confined to the surface layer of organic-rich sediments, where they can take advantage of steep chemical gradients of S and oxidants (e.g., nitrate and oxygen). To bridge the spatial or temporal gap between S and oxidants, bacteria have developed interesting adaptations such as the motility and storage of both nitrate and elemental S in the cells and the formation of several-centimeter long chains, i.e., cable bacteria, conducting electron currents (Schulz and Jørgensen, 2001).

Disproportionation of sulfur

In the latter part of the twentieth century, investigators discovered that not only can bacteria oxidize and reduce S, but they can also disproportionate it. Disproportion reactions are best likened to a fermentation in which one portion of a molecule acts as an electron donor and the other, an electron acceptor. Bacteria capable of S disproportionation can be found in *Desulfovibrio*, *Desulfobacter*, and *Desulfocapsa* spp., among others. Bacteria are able to disproportionate thiosulfate, in which the S atom that carries a +5 charge is oxidized to one with a charge of +6. This S^{6+} is released as SO_4^{2-} . Simultaneously, bacteria oxidize the other S atom in thiosulfate that carries a -1 charge to one with a charge of -2. This S^{2-} is released as hydrogen sulfide:

This metabolic process has immense implications for the global S cycle since typically in sediments sulfate predominates in the upper layers and sulfide in the lower layers. Hence, this metabolic reaction reveals an entirely new and, previously unsuspected

ecological niche, which is responsible for up to 60% of the thiosulfate transformations in sediment. Since then, other bacteria have been found that can disproportionate sulfonates such as taurine to sulfate and sulfide. The bacteria capable of this organic S disproportionation reaction form a new species called *Desulfonisporea*.

In contrast to the disproportionation of thiosulfate, the disproportionation of S^0 is not thermodynamically favorable. Low concentrations (<1 mM) of sulfide products, which usually require scavenging with iron or manganese, can make S^0 disproportionation thermodynamically favorable (Finster, 2008). The net stoichiometry of S^0 disproportionation is:

however, this net stoichiometry will change if sulfide is scavenged by iron:

Disproportionation is a mechanism for depleting ^{34}S in sedimentary sulfides. The disproportionation of S^0 produces ^{34}S -depleted sulfides and ^{34}S -enriched sulfates relative to S^0 . The sulfide produced by this process is reduced by approximately 4–9‰ relative to S^0 . Thus, the production of ^{34}S -depleted sulfides would increase with repeated cycles of sulfide oxidation to S^0 and S^0 disproportionation.

Reduction of sulfur

The reduction of S can occur for two reasons: assimilation and dissimilation. The assimilation pathway has been discussed above – bacteria convert sulfate to sulfide for inclusion in amino acids such as cysteine. Dissimilatory sulfate reductase refers to a process whereby sulfate is used as a terminal electron acceptor. Sulfate-reducing bacteria use such an enzyme, which allows them to oxidize H_2 or organic substrates such as lactate, malate, acetate, succinate, fumarate, fructose, glucose, fatty acids, and ethanol, and use sulfate as a terminal electron acceptor. Hence, these bacteria are primarily found in environments where there is little or no oxygen and live off the fermentation end products produced by other bacteria. Sulfate-reducing bacteria catalyze the following process (Fig. 3; bottom side):

In this process, sulfate is transported into cells by sulfate transporters and becomes activated with ATP in the cytoplasm by ATP sulfurylase to form APS. The APS is reduced by adenylyl-sulfate reductase (Apr) to form sulfite, and the (bi)sulfite is further reduced by (bi)sulfite reductase (Dsr) to finally form H_2S . Then, H_2S diffuses extracellularly through the cell membrane.

Since hydrogen sulfide is extremely toxic, these organisms require some sort of metal to react with the hydrogen sulfide produced and precipitate as an insoluble metal sulfide. In soil, this metal is typically iron in the form of FeS, which is often found in areas occupied by sulfate-reducing bacteria. The reaction catalyzed by sulfate-reducing bacteria reaches an optimum at an E_h of -300 mV at a pH of 7. These conditions are typically reached in the strictly anaerobic zones. Typically, terminal electron acceptors are depleted in the following order: oxygen, nitrate, nitrite, manganite, iron, sulfate, and finally, carbon dioxide. Thus, there are many alternative electron acceptors that will be used by a microbial community before sulfate is reduced. Despite this limitation, sulfate-reducing bacteria and their activity are commonly found in soils, sediments, polluted water, oil-bearing strata, and shales.

Sulfate-reducing bacteria can implement an alternative survival strategy if sulfate levels in the water are too low to be used. The H^+ produced by organic matter oxidation is transferred directly to a methanogen which then consumes that H^+ to reduce CO_2 and produce methane. Because the methanogens keep the partial pressure of hydrogen so low, the sulfate-reducing bacteria can use this mechanism to obtain energy from organic matter degradation even when there is not enough sulfate around them to transform to sulfide. It is estimated that 3–4% of the global flux of organic carbon flowing to the seafloor is converted to methane. Methane then diffuses upward and is quantitatively oxidized by anaerobic methanotrophic archaea upon encountering sulfate serving as the electron acceptor (Reeburgh, 2007):

Sulfur transformations and environmental quality

The biological transformations of S can lead to significant environmental problems in the soil. The enzyme sulfate-reducing bacteria use to transfer methyl groups can also accidentally methylate mercury to form methylmercury. Sulfate-reducing bacteria have been identified as one of the primary causes of the increased mercury accumulation in many ecosystems because methylmercury is the form of mercury that most readily accumulates in food chains. Typically, this reaction occurs in anaerobic, lowland soils where the activity of sulfate-reducing bacteria is closely linked to methylmercury production. However, sulfate-reducing bacteria can also mitigate environmental pollution through the production of metal sulfides by the following reaction:

Sulfate-reducing bacteria like *Desulfovibrio* spp. can form sulfides of Sb, Co, Cd, Fe, Pb, Ni, and Zn during the reduction of sulfate. The extent of metal sulfide genesis depends on many factors, such as the amount of sulfate present and the relative toxicity of the metal ion. In nature, this toxicity is reduced when the metal ions are adsorbed on clays or complexed with organic matter. The oxidation of metal sulfides in soil involves both chemical and microbial processes and, as a result, is a more complex process than is the oxidation of S^0 . Chalcocite (Cu_2S), chalcopyrite ($CuFeS_2$), galena (PbS), pyrite (FeS_2), and nickel sulfide (NiS) are just a few examples of metal sulfides that are subject to microbial transformations. For example, the biological oxidation of pyrite (FeS_2) can follow one of two pathways. The first pathway follows a series of oxidation steps, described in Eqs. (9) to (12). The second mechanism of pyrite oxidation involves thiosulfate as an intermediate but in the end requires the oxidation of elemental S to sulfate by *Thiobacillus*. These biotic oxidations are responsible for the formation of acid mine drainage and acid soil formation in surface mine spoils. First, ferrous sulfate is formed as the result of an abiotic oxidation step:

This reaction is then followed by the bacterial oxidation of ferrous sulfate, generally by *T. ferrooxidans*:

This reaction occurs chemically but can be accelerated 10^6 – 10^8 times by thiobacilli. This bacterial oxidation of ferrous iron plays an important role in the bioleaching of metal sulfides in the environment because it cycles the iron between +2 and +3 and the iron is then free to oxidize sulfide minerals abiotically.

Subsequently, ferric sulfate is reduced and pyrite oxidized by a strictly chemical reaction:

The elemental S is finally oxidized by *T. thiooxidans*, and the acidity produced helps the whole process to continue.

Note the net production of 10 molecules of H_2SO_4 during the process.

Although several S-oxidizing thiobacilli and heterotrophs can be isolated from acid sulfate soils in which pyrite is being oxidized, they appear not to play an important role in the process, with the exception of *T. ferrooxidans*. The biological oxidation of sulfides and other reduced S compounds can have severe consequences for the environment. For example, acid mine drainage contaminates several thousand kilometers of streams in the Appalachian coal-mining region of the USA.

Conclusion

There is a large amount of S present in soil and most of it is found in a form susceptible to biological transformations. These transformations include mineralization, assimilation, oxidation, and reduction. Since the industrial revolution, anthropogenic activity has impacted the S cycle by increasing the deposition of sulfate in the form of acid rain and by exposing more S to oxidation during mining operations. The four basic transformations discussed in this article influence the fate of the movement of S in terrestrial and aquatic ecosystems and the environmental impact of anthropogenic activities altering the S cycle.

Abstract

Plants require essentially the same set of elements for normal growth, acquired mainly as ions from the soil environment. Yet soils vary widely in their capacity to supply these ions due to large variations in soil development and inherent heterogeneity within the soil system. Roots predominantly access nutrients from the soil solution phase but concentrations are low, thus replenishment from the solid and, depending on the nutrient, the gaseous phase, is important. Roots and ions must also come into contact so that uptake can occur, and the responses of roots and the movement of ions will be discussed.

Key points

- Nutrients (macro- and micro-nutrients) essential for plant growth and development.
- The five factors of soil formation, and how these impact nutrient availability.
- Nutrients in the soil-plant system as influenced by the particular ion and the different phases (solid, solution and gaseous), the organic and mineral components of soil and the microbial population.
- Root-ion contact including movement of ions to the root.
- Root responses to nutrients including ideotype root traits for acquisition of N and P and mycorrhiza colonization.

Introduction

Despite the vast diversity observed among green plants, they all require the same set of essential elements to grow, develop and successfully complete their lifecycle. These elements can be further grouped into the so called ‘macronutrients,’ because plants require these elements at relatively large concentrations, and the ‘micronutrients,’ which, as the name suggests, are required at much smaller concentrations, but, nevertheless, are still essential to ensure the plants lifecycle can be completed. In reality, demonstrating that elements are actually ‘essential’ can be problematic especially in the case of those that are required in such small amounts analytical detection may be difficult or may be subject to contamination issues. Indeed, it is only relatively recently that nickel (Ni) was added to the ‘essential’ element list (Brown et al., 1987) and others may still yet be identified and subsequently included.

While plants can obtain some of these essential elements, such as carbon, oxygen and hydrogen, through photosynthesis, the majority are mainly acquired as ions from the soil environment (Fitter and Hay, 2002; Table 1). The elements shown in Table 1 are required by plants for the same essential functions and when plants are unable to take up these elements in sufficient quantities then nutrient deficiencies occur. Many symptoms of different nutrient deficiencies however, can look remarkably similar with, for example, interveinal chlorosis (i.e., where yellowing of leaf tissue between the veins occurs while the veins remain green) being indicative of magnesium, iron, or manganese deficiency. Symptoms of nitrogen and sulfur deficiency, which, in both cases involves yellowing of the leaves, may also appear very similar and, as such, hard to distinguish, especially during the early stages of deficiency. While the location (i.e., whether in young or old leaves) of the deficiency symptoms may also provide an indication of the particular nutrient in question (and its associated mobility), it often can be difficult to decipher the exact nutritional problem by visual observation alone. While, in other cases, such as is frequently the case for phosphorus deficiency, visible symptoms may not be obvious even though phosphate supply may be limiting for the plant. If deficiency symptoms are not identified early enough and remedial action taken, then large crop losses may occur. In some cases, such as in the case of boron deficiency, such crop losses cannot be recovered by later applications. Nutrient deficiency symptoms may also look slightly different depending on the plant species in question and should always be compared with a healthy specimen of the same species. Under field conditions further

Table 1 The elements, with the exclusion of carbon (C), hydrogen (H) and oxygen (O) which are incorporated during photosynthesis, required for healthy plant growth, their typical concentrations, main function and deficiency symptoms.

Element	Typical concentration in plant tissue ($\mu\text{g g}^{-1}$)	Main function	Deficiency symptoms
Macronutrients			
Nitrogen (N)	20,000	Constituent of amino acids, hence proteins, and of chlorophyll.	Stunted growth and chlorosis; Yellowing of older leaves; Also pink-purple tints to stems, petioles, leaves.
Phosphorus (P)	2,000	Nucleic acids (e.g. DNA, RNA); Adenosine triphosphate (ATP); Membranes (i.e. fatty phospholipids)	Leaf tips have a burnt appearance; Leaves have an intense green or reddish-purple coloration.
Potassium (K)	10,000	Electric charge balance in cells; Osmoregulation.	Leaf tips with brown or burnt appearance; Area between leaf veins becomes yellow or white in appearance while veins are green (called interveinal chlorosis)
Calcium (Ca)	500–5,000	Cell wall and membrane integrity and function; Second messenger.	New leaves have twisted or stunted appearance; Causes blossom-end rot (fruit with a dark spot at bottom).
Magnesium (Mg)	200–2,000	Constituent of the chlorophyll molecule; Required for numerous enzyme reactions; Control of cation - anion balance.	Yellowing of older leaves between leaf veins (i.e. interveinal chlorosis)
Sulfur (S)	1,000	Component of many primary and secondary plant metabolites including some amino acids.	Chlorosis and yellowing of young leaves sometimes followed by older leaves.
Micronutrients			
Iron (Fe)	100	Operation of redox systems; Chlorophyll synthesis.	Interveinal chlorosis in young leaves.
Manganese (Mn)	50	Various including: Redox processes; Chlorophyll formation; Photosynthesis; Respiration; Cell division.	Interveinal chlorosis in young leaves; Sometimes with tan or dark spots on chlorotic areas; Plant growth stunted.
Boron (B)	20	Diverse roles including: Cell wall formation and stability; Integrity of membranes.	Depression of growing points (root tips, buds etc.) and stunted/deformed growth.
Zinc (Zn)	20	Enzyme functioning; Membrane structure; Plant hormones (e.g. auxin).	Interveinal chlorosis particularly in younger leaves. May have necrosis spots. Terminal leaves may be more clustered in rosette form.
Copper (Cu)	5	Redox reactions.	Plant is stunted; Leaf tips may turn blueish-green color or brown depending on plant species.
Chlorine (Cl)	1,000–10,000	Various including roles in osmotic and stomatal regulation, Evolution of oxygen in photosynthesis etc.	Wilting and curling of leaves at margins; Chlorosis then necrosis in severe cases.
Molybdenum (Mo)	0.2	Enzymes of N metabolism.	Older leaves more affected and have yellow appearance; Rest of the plant may become light green.
Nickel (Ni)	0.5	Enzymes of N metabolism.	Necrosis of leaf tips; Chlorosis of younger leaves.

Adapted from Fitter AH and Hay RKM (2002) *Environmental Physiology of Plants*. (3rd edn.). London: Academic Press.

complications arise including more than one nutrient may be deficient at the same time; one element may be limiting and another at excessive (toxic) levels; plants may also be subject to pathogen attack; all of which may further complicate the correct identification of any nutrient deficiency to which the plant may be subject. Consequently, analytical analysis of leaf material to confirm the limiting nutrient is normally advised. This is particularly important in an agricultural context to provide the appropriate addition to alleviate the nutrient deficiency without exacerbating other issues given that the difference among deficient-adequate-toxic levels can be quite narrow.

In addition to the 'essential' elements there is another class often referred to as 'beneficial' elements. Examples of beneficial elements are silicon (Si), sodium (Na), cobalt (Co), aluminum (Al) and selenium (Se). The members of this class can stimulate plant growth or promote survival but are considered non-essential for plants to complete their life cycle. This is despite the fact that these 'beneficial' elements may be essential for some plant species (e.g., such as Si in horsetail (*Equisetum spp.*) and some C4 species), or under certain specific conditions (e.g., Co to ensure nitrogen-fixation rates in plant-bacterial nitrogen-fixation associations given Co is a component of the coenzyme cobalamin (vitamin B₁₂) required by nitrogen-fixing bacteria).

Unsurprisingly, therefore, the definition between what constitutes an essential versus a beneficial element has long been a controversial topic, and perhaps the arguments on this subject have been most passionately debated in the case of Si (Epstein, 2009; Coskun et al., 2019). Plants can be grown to maturity and complete their life cycle when grown in solution culture containing no Si source, hence, Si does not meet one of the key classical criteria for being classed an 'essential' element. However, Si uptake and its subsequent accumulation in leaves and stems has often been found to enhance growth through, for example, an increased erectness of leaves, improved light interception and enhanced photosynthetic rates. Furthermore, Si uptake enables plants to tolerate abiotic

and biotic stress in the field (Coskun et al., 2019) which may, in turn, be fundamental to the very survival of the plant in that environment. Thus, while Si may not be classified as essential in a nutritional context, it may be considered 'quasi-essential' for plants when under stressed conditions (Epstein, 2009).

When ions are at the root surface they can then be taken up by the plant. Selective uptake of ions occurs so that the plant can both accumulate ions it requires at higher levels than that in the soil solution and reduce or exclude those ions that it requires in lower amounts or that may be harmful. Uptake into the root may occur via diffusion (passive diffusion or facilitated or restricted by transport proteins) or by active transport. However, before ion uptake can occur, first, roots and ions have to encounter each other and it is the factors that influence ion availability and these encounters that will be discussed in this chapter.

Soil formation factors impact upon nutrient availability

Soils vary widely in their capability to supply the elements shown on Table 1 due to the interactions among the five factors of soil formation namely parent material, climate, topography, organisms and time, with the latter being the time the other four factors have had to work on the system. As soils age, nutrient levels tend to decline due to losses through leaching or erosion processes, consequently, some of the most ancient soils on earth, such as those found in parts of South Africa and Australia, are also among the most nutrient impoverished. However, some soils can also become rejuvenated and nutrient levels can increase through, for example, deposition of material from elsewhere, glaciation events and so forth.

The parent material is the initial state of the system from which the subsequent soil develops. The climate that the parent material is under influences how rapidly the parent material weather and thus, how quickly soil formation occurs with warm, moist climates increasing soil development compared to cold, dry climates. The parent material is composed of mineral or organic material or both and can be considered, with the notable exception of nitrogen, as setting the upper limit for the nutrient content of the soil. Nitrogen levels are the exception because N can enter the soil through fixation from the atmosphere. Although weathering of rocks was previously considered to release only negligible amounts of nitrogen, more recently this viewpoint has been questioned with the evidence that rocks, particularly sedimentary rocks, may release more N to soils than previously realized (Houlton and Morford, 2015; Houlton et al., 2018). This in turn, has led to suggestions that this may have implications for global climate change predictions if the capacity of plants to respond to elevated CO₂ levels are not so constrained by N limitations to growth and development as previously thought (Houlton et al., 2018). However, whether these effects actually result in global, rather than local, impacts still has to be fully determined, but may help to explain why some younger soils contain more N than perhaps would be predicted based upon estimates of nitrogen fixation alone.

Soil that is derived from different parent materials can have distinctive properties. For example, soils formed from limestone are, at least initially, very base-rich while those formed on granite or sandstone are very base-poor. Parent material which is base-poor has a tendency to be predisposed to acidification and podzolization processes especially in climatic areas that are cool and with considerable precipitation. In areas where the vegetation is coniferous forest, an acidic humus is produced. The acidic humus reduces microbial decomposition as well as earthworm activity so that the layers (or horizons) of the soil profile are not merged and instead tend to be sharply defined. Podzols have a grey or light colored 'E' or eluvial horizon due to severe leaching (or eluviation) washing out everything except the silica (SiO₂) sand. Instead, the aluminum and iron oxides accumulate in the lower, subsoil horizons. The accumulation of the iron oxides may result in a hardpan layer forming which, in turn, can impede water drainage. While podzols can be found at all elevations, topography is another important factor which influences the rate and type of soil formation, e.g., soils on slopes tend to suffer from erosion so have a tendency to be shallower than soils at either the bottom or top of hills. Soils at the bottom of hills also tend to be more nutrient-rich due to downward movement of nutrients as a result of erosion or leaching processes. The topography of an area can also have an important impact upon the biodiversity of the plant species present. For example, in fen peats, where the plant species present are controlled by the soil water chemistry, if the topography allows the accumulation of base-rich ground water above limestone rock the dissolved calcium contained within the water acts as a pH buffer to maintain a more basic pH which, in turn, enables more plant species to survive in these particular ecosystems and so promotes biodiversity.

The impact of organisms (including humans) on soil formation is complex. Humans have a large impact upon soil formation through large scale changes to land-use including conversion of natural areas for agricultural production and the subsequent intensive management practices these normally entail. Other organisms including other animals, microorganisms and plants also impact on soil properties through bioturbation activity or altering the chemical environment through the release or selective uptake of substances from the soil. Studies on the Glacier Bay region in south eastern Alaska have proved to be useful to study soil development over relatively short timescales given records of the glacier retreat exist, and thus, the ages of the glacial moraines are known. This helps facilitate the study of soil properties that relate directly to the vegetation. The plant species that are present in soil systems may produce litter inputs that are acidic or basic which, in turn, will influence the organisms that will be able to persist under these altered soil conditions. At Glacier Bay it was found that under alder the uppermost soil horizons had a dramatic reduction in pH from 8.0 or more, to pH 5.0, within a 35 to 50-year period. In contrast, other plant genera present (such as *Salix* and *Populus*) did not demonstrate such a dramatic impact upon the soil pH as alder (Crocker and Major, 1955). With time, spruce replaces the alder at Glacier Bay thus the impact of organisms also involves ecological succession where the mix of species and the habitat changes over time. Plant species present are also impacted by the climate thus emphasizing that the factors that influence soil formation should not be considered in isolation from each other.

Nutrients in the soil-plant system

The five factors of soil formation result in variations in soils within the landscape but variations at a more local level, and at scales relevant to plant roots, can also occur. Thus, while soil development helps explain the variation among different soils to supply nutrients to plants, generally much shorter time scales are relevant over the lifetime of a plant. Plants have to acquire the majority of their nutrients from the soil and soils are complex environments, comprising solid, liquid, and gas phases. Plant roots predominantly obtain their nutrients from the soil solution phase but concentrations of ions in the soil solution phase are generally small, thus the rate at which this nutrient supply is subsequently replenished becomes important. Mineral nutrient cycling in soil systems involves losses, inputs and transfers among components of the nutrient cycle but it is the equilibrium among these three different phases that largely impacts upon actual nutrient availability for the plant which, in turn, depends on the nutrient in question. For example, in the case of nitrogen, inputs may be via biological fixation of N_2 from the atmosphere or wet (in the form of nitrate (NO_3^-) and ammonium (NH_4^+)) and dry (nitrous oxides (NO_x), and ammonia (NH_3)) deposition whereas losses may occur due to NH_3 volatilization, denitrification and leaching of highly mobile NO_3^- ions. Both NH_3 and NO_x are emitted from the burning of fossil fuels. Agricultural systems also contribute to NH_3 emissions predominantly due to livestock manures and both organic and inorganic fertilizer additions. Moreover, these N forms are not necessarily returned to the same system from which they were originally emitted and can cause problems if deposited on naturally N-sensitive soils resulting in a dramatic reduction in the biodiversity of the plant community as well the diversity of other species associated with that community. Furthermore, NO_x , together with sulfur dioxide (SO_2), which is also emitted predominantly from the burning of fossil fuels, can react with water and oxygen in the atmosphere to form nitric and sulfuric acid respectively which could then fall as precipitation: a phenomenon commonly referred to as acid rain. Acid rain can fall on plant-soil systems at some considerable distance from the original source of the emission and in addition to increasing the acidity of the soil can reduce the fertility of affected soils through leaching of calcium and other base cations. Other impacts upon soil chemistry include an increase in accumulation of N and S, increased Al mobilization and an increase in Al levels in the soil solution. The latter can subsequently negatively impact upon plant growth as well as potentially leaching into water courses and causing further environmental problems. The impact of acid rain upon soil chemistry will, however, depend upon the buffering capability of the particular soil experiencing the acid deposition. Well buffered soils will be less prone to these changes than soils that have low buffer power. The gaseous phase is thus clearly important in N cycling, in common with other element cycles such as carbon and sulfur. In contrast, there is no gaseous phase in the phosphorus cycle and so no significant quantities of phosphorus in the atmosphere.

Most ions in soil occur not in the solution phase that plants mainly access but, rather, in the solid phase as a component of soil organic matter or inorganic soil minerals. For example, while the total soil P content may be relatively large, the concentrations in the soil solution are typically only c. 0.1–10 μM (Schachtman et al., 1998; Hinsinger, 2001), and it is these small concentrations to which the plant has access. Mineralization of organic material releases nutrients including N, P and S into the soil-plant system some of which will enter the solution phase. Mineralization is carried out by a wide range of soil animals and microorganisms. However, while microorganisms play a central role in transformation and accessibility of N, the supply of P tends to be dominated instead by inorganic equilibria because of the propensity of phosphate ions to react with charged surfaces including organic matter and the dominant cations in most soils (i.e., Al^{3+} , Fe^{3+} or Ca^{2+}). The resulting adsorption of phosphate ions to these surfaces leads to sequestration of P in the solid phase into both labile and non-labile pools. Of these two, the labile P pool is less strongly adsorbed so is more likely to come into the solution phase and is in equilibrium with it. Over time some non-labile P will react to become labile P although much of the non-labile P will remain in this form and thus, inaccessible to the plant.

In the case of N, microorganisms play a central role in the transformation and accessibility of N forms in soils through the decomposition of complex organic compounds into more plant accessible forms. However, in most natural systems, mineralization rates tend to be slow and the subsequent conversion of NH_4^+ through to NO_3^- were generally considered to be the rate-limiting steps in the terrestrial N-cycle. Due to their rapid turnover times, rapid adaptation rate and proximity to the N-reaction sites, microorganisms are well positioned to utilize released inorganic N sources first, with the plant only being able to access what is left over after microbial uptake. Studies using ^{15}N labelled organic materials of varying complexity added as discrete zones or patches to the soil-plant system have shown that microbial sequestration of this N however, was only short term and that plants did capture most of the mineralized N from the organic material. This has been attributed to the longer lifespan of roots in comparison to most soil microbes (Hodge et al., 2000a).

Most transformations of N in soil also depend on the supply of carbon (C) and thus these two nutrient cycles are considered closely linked. The C:N ratio of the substrate determines the rates at which N (and C) are released and mineral N made available for plant uptake. Also influential are the composition of the decomposer microbial community and its requirements for N. Fungi tend to have a greater substrate assimilation efficiency and a smaller N requirement per unit of C assimilated than bacteria. Thus, if the decomposer population is predominantly fungal, more N may be released than if it was predominantly bacterial. However, fungi also tend to turn over less rapidly than bacterial populations, so the N contained in their structural components will be locked up, and hence unavailable for use by other organisms including plants, for longer than bacterial N. Generally net mineralization, which results in the release of N, occurs if the C:N ratio of the substrate being decomposed is less than approx. 25:1. At higher C:N ratios, net immobilization occurs and the microbial decomposer community requires additional N from the soil system to decompose the substrate. Net immobilization of N reduces the N available for the plant and can reduce overall plant growth. Although other factors influence the release of N, for example lignin content of the substrate, there is a strong inverse relationship between the amount of

Table 2 The percentage N captured by plants from organic material which in all cases was *Lolium perenne* shoot material but of varying C:N ratio.

plant N captured from organic substrates and the C:N ratio of the substrate, as shown in Table 2 from the same organic material (*Lolium perenne* shoots) but of varying C:N ratio.

Whereas the relationship between the C:N ratio of the substrate determines if net N mineralization or immobilization will occur is well established for N, this is not the case for P. Moreover, in forest surface soils net C, N and P mineralization are not closely linked. Differences in the reactivity of P versus N chemical forms with other ions in the mineral soil system together with increased microbial immobilization of N compared to P in both decomposing litter and organic horizons were thought to be responsible for this uncoupling between N and P mineralization (Brödlén et al., 2019).

In some ecosystems such as the arctic, alpine and boreal forest, annual plant N uptake was found to be higher than should be available through inorganic N capture alone. This led to the conclusion that many plant species in these ecosystems are accessing organic N sources directly without the prior need for microbial mineralization. Forms of organic N in these soils range from the complex (e.g., humus) to the simple (e.g., amino acids and urea), although most of the evidence for direct uptake of intact organic N compounds via plant roots comes from studies on amino acid N or small peptides and it is now widely accepted that roots from a wide range of plant species can take up these simple organic N forms directly. The findings of some other studies suggest that plant roots may release proteases to promote the breakdown of soil proteins and are also able to take up intact proteins into root cells, all without the involvement of any microbial activity (Paungfoo-Lonhienne et al., 2008). In most soils proteins are a considerable organic N reservoir, thus, such an N acquisition pathway could potentially be very important for the plant. However, microorganisms can also access these N sources so plant-microbial competition will occur for these soil N forms also. Moreover, the results from studies on root proteases are contradictory with some concluding that proteases activity was mainly root-bound rather than secretory and that the use of exogenous protein was an indirect by-product linked to other root functions rather than having direct involvement in plant N acquisition *per se* (Greenfield et al., 2020). Thus, the ecological importance of root produced proteases as an important N uptake pathway in plants has yet to be fully resolved.

Rather than competing with the plant for nutrient resources some microorganisms may aid nutrient capture by plants. Such associations can be rather loose, such as the plant growth-promoting rhizobacteria (PGPRs) which covers bacteria from a number of different species but which have been found to be beneficial to promoting plant growth. This can occur via a wide range of mechanisms including via an impact upon nutrient availability through, for example, enhanced phosphate solubilization or biological nitrogen fixation. PGPRs although present in the rhizosphere are only loosely associated with the plant. Much closer symbiotic associations are formed between plants such as legumes and alder and bacteria such as rhizobium and *Frankia* respectively. These bacterial symbionts form nodules on the roots which are capable of fixing dinitrogen and thus supply the plant with N directly. In return the bacteria obtain a supply of carbon from the plant principally in the form of organic acids. The majority of plants, however, do not form N₂-fixing symbiotic associations and must rely on N uptake via their roots or mycorrhizas which are associations between plant roots and soil fungi (see “Root responses” section).

In addition to microorganisms, soil animals also play an important role in the mineralization process through physical, chemical and biological processes. Soil animals can physically break up and redistribute organic materials in the soil. They also ingest organic materials which are subsequently broken down by a range of enzymes or by microflora present in their guts. Much of the C they consume is used for metabolic processes and the excreted waste products, in the form of NH₄⁺, urea, or amino acids, are a much more readily available form of N for plant uptake than the organic material originally ingested. Soil animals feed on microorganisms as well as other soil animals. The plant benefits from the regulation of the size and activity of the microbial population and from the release of more nutrients (including N and P) back into the soil-plant system: for example, an increase in plant N capture of up to 75% has been reported as a result of protozoan grazing on soil microorganisms (Clarholm, 1985). Thus, although microorganisms may initially sequester inorganic N, grazing by protozoa ensures that this N is released back into the plant-soil environment and becomes available for root uptake.

In terms of soil fertility, clays are the most important of the inorganic soil minerals solid phase because of their reactivity. Clays consist of aluminosilicate sheets composed of aluminum, silicon and oxygen held together by various cations (e.g., Al³⁺, Mg²⁺, Fe³⁺, Na⁺, K⁺). Where clays fracture, surfaces with a net negative charge are exposed. This negative charge is balanced by cations that are ‘held’ exchangeably on these exposed surfaces which gives rise to the cation exchange capacity (CEC) of the soil. Soil organic matter

also contributes to the CEC of the soil but in this case is due to the dissociation of organic acids resulting in a net negative charge which is then balanced by the cations present in the soil. This dissociation of organic acids is, in turn, influenced by soil pH such that a soil with a low pH will have a low CEC due to the organic matter fraction. The base saturation, i.e., the percentage of CEC sites occupied by base cations such as Ca^{2+} , Mg^{2+} , Na^+ and K^+ , can also be calculated and as base saturation increases, so does pH. Soils that have a high base saturation are therefore more strongly buffered against acid cations released by plant roots and through other soil processes, such as nitrification, organic matter decay and acid rain. In the more local vicinity of the soil directly surrounding the plant root the form of inorganic N taken up by the plant can strongly influence the pH of the rhizosphere. To maintain the electrochemical gradient between root cells and soil (cells typically have electrochemical potentials of less than -100 mV) which drives cation uptake, plants taking up N as nitrate will release bicarbonate (HCO_3^-) or hydroxyl (OH^-) ions, causing the rhizosphere pH to increase. In contrast, plants taking up ammonium as the main form of N will tend to release protons, causing the rhizosphere pH to decrease. However, even when grown on nitrate as the sole source of N, the rhizosphere pH of some plants (such as chickpea) can decrease. This decrease is almost certainly due to a higher ratio of cation to anion uptake. Leguminous plants with active N_2 -fixing nodules also tend to have a large cation to anion uptake ratio and so a tendency to excrete protons and so decrease the pH of their rhizosphere soil. Thus, the consequences for the rhizosphere pH will depend not only on the form of N (i.e., NH_4^+ , NO_3^- or N_2 fixation) the plant is taking up but also on the plant species present and the buffering capacity of the soil.

Overall, soil pH can have a large impact upon nutrient availability for the plant and soils with a low pH tend to have little calcium and magnesium availability. Other nutrients, such as molybdenum (Mo), are also affected and become unavailable and consequently Mo deficiencies may occur, while phosphate can react with iron and aluminum hydroxides also reducing its availability for the plant. Microbial, particularly bacterial, activity is also reduced at low pH thus slowing organic matter decomposition rates and reducing nutrient release particularly of available N. In addition, there are other problems associated with low pH including Al toxicity which can severely impact upon normal plant, particularly root, growth. Liming of acidic soils to increase pH can improve plant growth, yield and plant species richness and diversity as demonstrated by the Park Grass Experiment at Rothamsted, UK, the oldest ecological experiment in the World which has been running since 1856 (although regular applications of lime have only been applied since 1903; [Silvertown et al., 2006](#)). However, at high soil pH the availability of some nutrients also becomes problematic with, for example, phosphate forming insoluble compounds this time with calcium and magnesium. A slightly acidic to near neutral pH is generally considered optimal for the availability of most plant nutrients.

Although a small CEC means that more nutrients will potentially be in the soil solution rather than held on exchange sites this also means these nutrients can be lost from the soil system through leaching processes and so forth, thereby reducing the overall fertility of the soil. In contrast, soils with a large CEC will have a large nutrient reservoir but these nutrients will be strongly held on the charge surfaces and therefore unavailable to the plant. Thus, CEC gives an indication of the potential nutrient supply for the plant rather than the actual availability. The addition of cations to the soil (via liming, fertilizer etc.) results in some of these held cations being exchanged and hence coming into the soil solution so that they are potentially available for acquisition by plant roots.

Movement of ions to the root surface

For nutrient ions to be acquired by the plant they have to come into contact, and there are three main ways in which this may occur. The first is root interception, whereby roots growing through the soil come into direct contact with nutrients held on soil aggregates. Root interception has been found to be more important for some nutrient ions (such as magnesium) than others, however, given that roots typically only contact c. 1% or so of the soil volume the potential for root interception is rather limited. Moreover, any factor that has a negative impact on root growth (such as soil compaction) will also reduce the capacity for root interception. Thus, root interception is not considered a major mechanism for nutrient acquisition by the plant.

The second way in which contact between roots and ions may occur is via mass flow. Mass flow, or convective flow, is driven by the transpiration pull of the plant resulting in a water potential gradient. Water that moves to the roots to satisfy this transpiration demand will also contain soluble ions and these will be available for root acquisition. The mass flow of water is equal to the water that the plant transpires and that is subsequently released to the atmosphere. Transpiration rates can be substantial, e.g., in warm, forested areas between the tropics 32×10^{15} kg yr⁻¹ of water vapor passes through the stomata, a value that is equivalent to double the water vapor content of the atmosphere (see [Hetherington and Woodward, 2003](#)). The amounts of nutrient ions that can move by mass flow can be determined by the particular nutrient concentration in the soil solution and the water flux. If uptake at the root surface is greater than the rate of supply to the root surface by mass flow, then a concentration gradient will develop from the soil toward the root. Ions will then move down this concentration gradient toward the root surface via diffusion, which is the third way in which nutrient ions can move toward the root surface. Similarly, if movement by mass flow results in an oversupply of a particular ion at the root surface compared to plant demand, then diffusion of that ion will be away from the root surface. Although movement of ions via mass flow is generally a rapid process providing water flux and soil solution concentrations of ions is large enough, movement of ions via diffusion, by contrast, is a very slow process (see [Tinker and Nye, 2000](#) for a full discussion on this topic).

While both mass flow and diffusion represent the two main ways in which ions move to the root surface for subsequent root uptake, which is the more predominant movement pathway depends largely on the particular nutrient ion in question as well as the prevailing soil conditions. [Barber \(1974\)](#) estimated the relative contribution of mass flow and, by difference, diffusion, for Mg, Ca, P and K for a maize crop. Mass flow was more than adequate to meet the crops demand for Ca^{2+} and Mg^{2+} . This subsequently resulted in an over-supply of these ions which accumulated at the root surface as supply exceeded crop uptake. Diffusion occurs down a

Fig. 1 Schematic representation of the phosphate depletion zones that develop around a non-mycorrhizal root with root hairs (left) and a root colonized by arbuscular mycorrhizal fungi (AMF) (right) where the depletion zone is extended due to the AMF hyphae exploring a larger soil volume. The box above shows the uptake of phosphate across the plasma membrane and is common to both AMF hyphae and roots. Protons (H^+) are pumped out the cell by H^+ -ATPases on the plasma membrane to generate the proton-motive force to enable H^+ -phosphate co-transport by high affinity phosphate transporters at the root surface or extraradical mycelium (ERM) of the AMF hyphae. Reproduced from Hodge A (2017) Accessibility of inorganic and organic nutrients for mycorrhizas. In: Johnson NC, Gehring C, and Jansa J. (eds) *Mycorrhizal Mediation of Soil: Fertility, Structure, and Carbon Storage*. pp. 129–148, with kind permission from Elsevier Science.

concentration gradient, hence, in this case, diffusion of Ca^{2+} and Mg^{2+} was away from the root and therefore not an important supply mechanism for these ions. In contrast, mass flow supplied only 11% of the crop uptake of K^+ and less than 1% of P (as $H_2PO_4^-$) where supply by diffusion was more important. However, as noted previously diffusion tends to be a slower ion movement pathway hence ions cannot arrive quickly enough to satisfy the demand of the plant resulting in a zone of depletion developing from the root surface out into the surrounding bulk soil. The size and intensity of these depletion zones (i.e., the volume of soil the root effectively can acquire the ion from) depends on the particular ion in question and is also influenced by other factors including if the root is in a mycorrhizal symbiosis (Fig. 1).

The depletion zones that develop due to the diffusion of phosphate for example, are narrow and sharply defined. Hence, are extremely 'depleted' in phosphate. If the root is in mycorrhizal symbiosis however this depletion zone becomes extended due to the mycorrhizal fungal hyphae exploring a larger soil volume than the root alone (Fig. 1). If, prevailing conditions in the soil are such that mass flow fails to meet plant demand, NO_3^- will also move by diffusion. In contrast to the depletion zone for phosphate however the resulting depletion zone for NO_3^- tends to be both large and shallow. This means that even if movement is via diffusion, NO_3^- can still be effectively acquired by the plant. Hence, in the case of NO_3^- the problem is not movement to the root *per se* but if there are sufficient quantities of NO_3^- present in the soil.

Root responses

All plants face the same basic economic problem of where best to place their resources but are aided in this by being able to show a high degree of morphological and physiological plasticity at several organization levels: from cellular to between organs. Root systems are modular which allows them to be very plastic in their response to prevailing environmental factors, including the distribution of nutrient resources. When nutrient availability is low, plants generally increase their root weight ratio (RWR; ratio of root weight to total plant weight) because more biomass is allocated to the root system. However, the RWR is not necessarily the best root trait to measure for assessing the ability of plants to subsequently capture nutrient resources. The RWR will include old,

lignified roots not actively involved in nutrient uptake *per se*, and also changes in the architecture of the root system (i.e., the spatial configuration of the root system in the soil) in response to nutrient availability can occur independent of changes in root biomass. Uptake of nutrients is more closely related to root length than root mass, and a greater length of finer roots aids in the exploration of the soil environment (Hodge, 2004). Root mineral nutrient uptake is largely reliant on the absorption of ions from the soil that are transported to them by diffusion and mass flow. Beneficial physiological changes in ion uptake rates by roots can enhance uptake of mobile ions such as nitrate. In contrast, more immobile ions (e.g., phosphate) are limited more by diffusion to the root rather than uptake at the root surface so would be less affected by changes in root uptake rates. Although NO_3^- will move toward the root rapidly via mass flow if water flux and ion concentrations are large enough, if this is not the case then NO_3^- ions will move to the root via diffusion (i.e., down a concentration gradient). The diffusion coefficient for NO_3^- in the soil environment is approx. $10^{-10} \text{ m}^2 \text{ s}^{-1}$. In contrast, the diffusion coefficient for phosphate is approx. 10^{-13} – $10^{-15} \text{ m}^2 \text{ s}^{-1}$. The smaller diffusion coefficient of phosphate is due to the reaction of phosphate ions with charged surfaces and insoluble complexes formed with cations such as Al^{3+} , Fe^{3+} , and Ca^{2+} . Diffusion coefficients for NH_4^+ range between approx. 10^{-10} and $10^{-12} \text{ m}^2 \text{ s}^{-1}$, but the availability of NH_4^+ is further reduced by sorption in soil. Thus, the distribution of NO_3^- in soils should be more uniform than that of phosphate and, in principle, even a relatively low root length density (RLD) should be enough to capture sufficient N from the soil when present in the form of NO_3^- . In actuality, plants have to capture N, and indeed other nutrients, in competition with other plant roots as well as soil microorganisms, also a large number of inputs in natural systems occur in organic form via leaf litter, dead roots, and animals, leading to a heterogeneous distribution of resource supply both spatially and temporally. Thus, the distribution of resources in soil, even of NO_3^- , is not uniform but heterogeneous or patchy.

Root systems can respond to nutrient-rich zones or patches through proliferation of roots as demonstrated in the classic experiments conducted by Drew and colleagues in the 1970s. Barley roots exposed to a localized supply of nitrate, ammonium, and phosphate increased both the initiation (i.e., number) and extension (i.e., length) of first- and second-order laterals within that localized zone. Moreover, shoot weight was only slightly depressed when these nutrients were supplied locally compared with controls receiving a uniformly high supply of these nutrients throughout their entire root system. However, Drew's experimental system involved plants grown in sand units supplied with nutrient solutions and did not reflect the complexity of the soil environment. Moreover, responses observed under ideal, and often controlled, conditions may not necessarily relate to those that actually occur in the natural environment. Nevertheless, the study demonstrated that roots respond, often spectacularly, to inorganic N as well as phosphate-rich zones (Drew, 1975; Fig. 2).

The benefit of root proliferation in terms of increasing acquisition of immobile ions from the soil is relatively easy to interpret given the increased volume of soil explored. For mobile ions placing resources into increased root growth may appear counter-intuitive despite such root responses being widely reported. However, when two different plant species were grown in competition for resources from an organic N-rich patch (grass shoots dual-labelled with the stable isotopes ^{15}N and ^{13}C) added to soil, plant ^{15}N capture was related to RLD produced in the patch. No ^{13}C enrichments were detected in the plant tissue, therefore N must have been taken up as mineralized N (Hodge et al., 1999). Thus, when in competition for N, even when the N is in mineralized form and potentially highly mobile, RLD is important because the supply of N from the decomposing organic patch is finite. In contrast, in the absence of plant–plant competition, the supply of N can be thought of as invariant and RLD is less important.

Fig. 2 The proliferation of primary and secondary laterals of barley (*Hordeum vulgare*) root systems when supplied with a 100-fold greater concentration of phosphate, nitrate or ammonium to the middle part of their root system (indicated by the lines). H, high; L, low, which refer to the nutrient concentrations of phosphate, nitrate or ammonium received by the top, middle and bottom of the root system, respectively. The control which received uniformly high levels of nutrients to all parts of its root system is shown as a comparison. Reproduced from Drew MC (1975) Comparison of the effects of a localized supply of phosphate, nitrate, ammonium and potassium on the growth of the seminal root system, and the shoot, in barley. *New Phytologist* 75: 479–490, with kind permission of the trustees of the *New Phytologist* and Wiley-Blackwell.

Fig. 3 Root growth and proliferation in an N-rich organic material source added as a spatially discrete patch and comprising lyophilized algal cell organic material (C:N ratio of 3.2:1). (a) One day after the patch was added no roots in the patch zone were observed (b) 21 days after the patch was added, a single root was observed growing into the N-rich zone. (c) The same image 25 days and (d) 48 days after the patch was added: increased root production and root hair development in the N-rich zone was clearly observed. After 49 days, the plants were harvested and found to contain 54% of the N originally added in the algal cell patch in their tissues. Adapted from Hodge A, Robinson D, and Fitter A (2000) Are microorganisms more effective than plants at competing for nitrogen? *Trends in Plant Science* 5: 304–308, with kind permission from Elsevier Science.

The timescales to construct new roots in these nutrient-rich zones are generally weeks rather than days (Fig. 3). In contrast, microbial populations can respond much more rapidly in timescales of hours to days. Thus, root proliferation responses are considered to be more important in terms of plant–plant competition rather than plant–microbial competitive interactions. High-order laterals produced upon root proliferation also tend to have higher N concentrations and thus are more expensive to construct but presumably the benefits of exploiting a nutrient-rich patch and the capture of N from it outweigh the disadvantages of construction costs for these roots. Moreover, increased root turnover, i.e., a decrease in root longevity, is often observed in both fertile soils and fertile patches, but again presumably the advantages of having a young population of roots actively involved in nutrient-uptake processes outweigh the disadvantages of high root turnover rates. Plants can extract nutrients, including N, from root structures shortly after construction thus also considerably lowering initial construction costs.

A number of other root traits have also been demonstrated to be important for exploiting the soil environment for particular nutrient resources, although most research has focused upon the acquisition of the macro-nutrients P and N. The ideotype root traits for enhanced phosphate capture may include shallow basal roots with small diameter, increased specific root length (SRL), long and dense root hairs and arbuscular mycorrhizal (AM) associations. Certainly, inhibition of primary root growth, but increased second-order lateral root growth resulting in a more branched root system with roots concentrated in the upper soil layers where most P sources are located, is frequently reported under low P conditions. Plants may also induce high affinity P transporters in roots and alter their internal biochemical pathways to conserve P when under P-stress conditions. Some plants may also release H^+ ions under P-stressed conditions which is suggested to increase the solubility of calcium phosphates through acidification in the locality of the rhizosphere (Hinsinger, 2001) although if soils become too acidic this also presents problems for the plant as previously discussed.

Some plants, such as *Brassica napus*, show a large increase in the release of organic acids such as the carboxylic acids, malic and citric acid from their roots under low P availability. This could aid in P acquisition through the carboxylic acids chelating with cations such as Al^{3+} , Fe^{3+} or Ca^{2+} and so releasing bound phosphates associated with these cations into the soil environment for subsequent plant capture. While in other plant species, such as those that can form cluster roots (i.e. short lateral rootlets that are closely spaced) or the functionally similar dauciform roots (i.e. short lateral roots with dense clusters of root hairs), there is a marked, tightly regulated release of carboxylates including malic and citric acid that displace the held P so that it can be taken up by the dauciform or the cluster roots aided by the large surface of the clusters of root hairs (dauciform roots) or rootlets (cluster roots). Cluster roots may also release enzymes that enable organic P forms in the soil to be broken down while the carboxylic acids may also play a role in the hydrolysis of organic P forms. Thus, this would give these plant species access to P sources not normally available. This P acquisition strategy including the directed release of carboxylic acids is costly to the plant but it does allow these plants to extract P from forms that would not normally be available and hence allows these plant species to grow in extremely P-impoverted soils.

In contrast to the root traits that help increase P acquisition, the root trait ideotype for N acquisition involve a steep growth angle of crown roots, architectural and anatomical traits that reduce the cost of exploration and deep root placement in the soil to capture leached N, or ‘steep, cheap and deep’ root traits (Lynch, 2013). As these are ideotypes not all plant species show all these traits and there may be further trade-offs for example, in the case of P acquisition between root hair density and the formation of mycorrhizal associations. Moreover, plants need both N and P as well as the other macro- and micro-nutrients of varying mobility for normal

plant growth and function. Thus, further research is required to ensure breeding for the most appropriate traits for the particular environmental conditions in question but, nevertheless, root trait selection for crops that reduce the cost of soil exploration while promoting climate-resilience are urgently required to help ensure long term food security (Lynch et al., 2022).

Many plants rely on associations with mycorrhizal fungi to help acquire nutrients. Mycorrhizal fungi are important ecosystem engineers and can provide a range of benefits for their host plant including enhanced water relations, improved soil aggregation and reduced disease occurrence in addition to nutritional benefits. It is not surprising therefore that promotion of mycorrhizal associations is often suggested as a means to promote agriculture sustainability. Mycorrhizal associations are widespread with greater than 80% of plant species forming some type of mycorrhizal association. The arbuscular mycorrhizal (AM) association between fungi of the Mucoromycota subphylum Glomeromycotina and about two-thirds of all land plants is the most ubiquitous, and, together with mycorrhiza-like associations with fungi of the Mucoromycota subphylum Mucoromycotina, are contemporaneous with the early land plants (Feijen et al., 2018). It is well established that AM fungi aid their host plant acquire poorly mobile nutrients such as phosphate through the small diameter fungal hyphae exploring a larger volume of soil, including accessing soil pores that would otherwise be inaccessible to plant roots, at a reduced C cost compared to new root construction (Hodge, 2017). The inorganic P then has to be taken up by the AM hyphae (or indeed the roots) against a steep electrochemical gradient due to the difference in concentrations between that in the soil versus those inside the AM hyphae or roots. This is achieved by H⁺-phosphate co-transport via high affinity phosphate transporters (as shown in Fig. 1). Under P-deficient conditions AM colonized plants generally show increased growth compared to their non-mycorrhizal counterparts but when P levels improve then AM plants may do no better and may even show repressed growth. However, even when total plant P is not enhanced the contribution of the AM fungi to plant P acquisition may still be substantial. For example, while some plants demonstrate no growth response, or improved total P acquisition, as a result of colonization by different AMF fungi, application of the radioisotope, ³³P, revealed that the AM fungi may still be responsible for most, if not nearly all, of the P acquired by the plant (Smith et al., 2004). AM fungi can also help plants acquire N, predominantly in inorganic forms. The values of the contribution of this N to total shoot N however vary considerably: from a few percent to c. 75% depending on the environmental conditions including that of water availability (see Hodge and Storer, 2015 for a review on this topic). AM associations can also help with plant acquisition of other nutrients such as sulfur and zinc, but again values vary considerably among studies suggesting diversity among AM fungi in their nutritional benefit which may also differ depending upon the prevailing environmental conditions (Giovannetti et al., 2017; Cavagnaro, 2008).

Over evolutionary time, various transitions have resulted in the occurrence of other mycorrhizal associations, such as the ectomycorrhizal (EcM), ericoid (ErM) and orchid types, adapted to the prevailing environmental conditions although the AM symbiosis remains the most prevalent among plant species. In contrast to the AM association, the EcM association involves a much smaller number of plant species (c. 6000), but a much larger number of fungal species (c. 20,000). Most of these plant species are woody species, hence, although the EcM association only involves c. 2% of plant species (van der Heijden et al., 2015), it is of economic as well as ecological importance. The fungal species involved in the EcM symbiosis are from the Basidiomycota and Ascomycota fungal phyla and have evolved multiple times from saprotrophic ancestors. Consequently, the capability of these fungi to acquire nutrients from complex organic sources is equally diverse with some (but by no means all) having the ability to operate oxidative decomposition pathways to release nutrients including N and P for their host plant. The ericoid (ErM) association has an even more limited host plant range and involves only c. 1% of plant species (comprising mainly members of the Ericaceae and some liverworts). The fungi are mainly from the Ascomycota but also include some Basidiomycota. These fungi have been demonstrated to access organic forms of nutrients through their enzymatic capabilities reflecting the nutrient sources prevalent in the environments in which this association is found. Thus, in both the ErM and EcM associations the mycorrhizal fungi may allow the plant access to nutrient sources that would otherwise be inaccessible.

Conclusion

Variability in nutrient supply among and within soils has a large impact upon plant growth. Nutrient ions which are essential for plant growth and development, have widely contrasting mobilities depending on the degree of interaction with the prevailing soil environment. For some ions that barely interact with charged surfaces in the soil the impact is slight, while for others movement is severely impeded. Ions with high mobility can move readily to the root surface via mass flow providing water flux and ion concentrations are high enough, otherwise movement is via the much slower pathway of diffusion. Diffusion down a concentration gradient is the main way in which immobile ions move to the root. However, as diffusion is a slow ion movement pathway, ions do not arrive fast enough to satisfy plant demand so a depletion zone develops around the root. The size of this depletion zone is important as it determines the volume of soil the root effectively has access to for that particular ion. It is therefore unsurprising that plants have evolved a number of strategies to help them acquire limiting nutrients from their environment. These include changes in the root system architecture (RSA), chemical extraction and associations with microorganisms from the relatively loose association with PGPRs in the rhizosphere to the tight symbiotic associations with nitrogen-fixing bacteria and mycorrhizal fungi. These strategies also represent targets for enhancing sustainable crop food security in the future through, for example, the application of microbial inoculants or genetic modification of RSA. If these strategies are successful or not will depend upon if the environmental context (i.e., organic versus inorganic additions, mono- versus mixed cropping, multi-ion environment and so forth) is also considered as not all will work in all types of soils and under all circumstances.

Abstract

Research focused on root traits and functions has expanded in recent decades and findings have identified how specific traits influence plant performance under environmental stressors, including drought, compaction, nutrient limitation, and salinity. Integrating global information has advanced understanding of how roots drive ecosystem functions, such as productivity, water and nutrient cycling, and erosion. Studies on anatomy and control of root growth are elucidating root response to changing environments. Modern methods in quantitative genetics and genomics enhance understanding of genetic underpinnings of root traits and functions. Advanced understanding of root form and function has important implications for ecology and land management.

Key points

- Roots are essential components of plant strategies.
- Growth and development of roots is governed by genetics and hormones and root responses to their environments.
- Trade-offs in root form and function influence how plants interact with soils and cope with environmental stressors such as drought, salinity, and nutrient limitation.
- Root traits influence various ecosystem functions such as nutrient cycling, productivity, and erosion.

Introduction

Many aspects of root form and function, including root architecture, morphology, physiology, and growth, are important for exploration of soil for water and nutrients. Root systems are comprised of segments with unique properties and a complexity that is often under appreciated. Research continues to uncover distinctive functions associated with root segments that vary in anatomy, morphology, and physiology. Several important concepts govern the development of roots and their direct and indirect effects on plant growth:

- 1) Plants construct roots of various forms and characteristics to optimize resource acquisition in particular conditions.
- 2) Trade-offs exist in root form and function with the costs of producing roots yielding benefits in terms of the acquisition of soil water and nutrients and ultimately, plant growth, and fitness.
- 3) Enormous variation exists among plant species in their root responses to abiotic (e.g., drought, salinity) and biotic (e.g., competition, pathogens) stress.
- 4) Genetic analyses have revealed that root architectural traits are often multi-gene or quantitative traits.
- 5) Root traits and functioning influence attributes of soil environments, plant communities, and ecosystems.

Root anatomy, development, and classification

Given the unique viewpoints from which researchers study roots, numerous schemes have been adopted to classify components of root systems. Here we first briefly discuss root anatomy, developmental-based schemes of root classification, and hormonal control of root growth. We then highlight functional traits and functional classifications based on root orders.

A cross-section of the mature root has several distinctive zones (Fig. 1a; Ranathunge, 2005), with characteristics that vary by root age, among different groups of plants, and among species. The epidermis is the outer layer of the root, which often has a protective exodermis immediately underneath it. The exodermis is composed of very compact cells with a Casparian strip composed of waxy substances, and suberin lamellae composed of glycerolipid polymers, both of which curtail apoplastic water flow, confining the flow of water to the symplast. This increases the selective uptake of nutrients, limits water flux out of the root, protects from microorganism intrusion, and further increases root mechanical resistance. These layers surround the cortex, which stores nutrients and supports colonization by mycorrhizal fungi (Comas et al., 2012). The endodermis is the innermost layer of the cortex, which also harbors a Casparian strip. Within the vascular cylinder, xylem tissues, including hollow tracheids, are important for transport of water and dissolved minerals to upper parts of the plant, and phloem elements, which conduct sugars and organic compounds from leaves to roots and other parts of the plant. In monocotyledon plants vascular bundles are organized in a circular pattern around a central pith. In dicotyledon plants xylem elements are present in the center of the root and are separated from phloem bundles by vascular cambium. The physical arrangement of xylem and phloem tissues can further vary among species. Within xylem tissues, protoxylem is the first formed elements of the primary xylem. Metaxylem is the part of the primary xylem that differentiates after the protoxylem but before the secondary growth if plants undergo secondary development. The pericycle is the outermost boundary of the vascular cylinder, located inside the endodermis. Lateral roots are initiated from the pericycle, and then grow outwards through the cortex and epidermis. The vascular cambium, which is responsible for secondary growth in roots, also originates within the pericycle in woody plants.

Root development begins at embryogenesis when embryonic plant cells give rise to seminal or primary roots. Many dicotyledonous plants develop one primary root, which thickens in some species due to secondary cambial activity, whereas most monocots develop several primary roots that do not undergo secondary growth. Embryonic plant cells also give rise to the quiescent centers and central root caps of these first roots. Several key zones become present in developing roots and remain present in root tips or apical zones as plants mature (Fig. 1b; Crang et al., 2019): the root cap that protects the meristem, the meristem itself, a region of elongation, and a region of maturation. Several processes are concentrated in this apical zone, including root elongation, the maturation of cells, and the development of vascular tissues, organs (e.g., root hairs, xylem elements, phloem elements), and lateral primordia, which give rise to lateral roots.

Roots branch in response to endogenous and exogenous factors. Numerous phytohormones, as well as biomolecules, regulate root growth and development (Jung and McCouch, 2013; Mukherjee and Baluška, 2021). The plant hormone, auxin, has a key role in the initiation of lateral root primordia. It can accumulate at the root apex, which usually exerts some degree of apical dominance,

Fig. 1 (a) Horizontal and (b) longitudinal cross sections of a root showing the different tissues, root sections, root features, and xylem and phloem elements. The outermost layer is the epidermis and root hairs, and the protective exoderms. In the cortex, there are intercellular air spaces between the cells. The endodermis surrounds the vascular cylinder, which contains the xylem and phloem. (A) Modified from Ranathunge KM (2005) *The Role of the Apoplastic Transport Barriers for Radial Water and Ion Uptake in Rice (*Oryza sativa* L.) and corn (*Zea mays* L.) Roots*. Doctoral thesis, University of Bayreuth, Faculty of Biology, Chemistry and Earth Sciences. (B) From Crang R, Lyons-Sobaski S, Wise R (2019) Roots. affects developing lateral root primordial, or both. Cytokinins, another class of plant hormones, inhibit lateral root formation. Low nutrient levels, especially low nitrogen levels, can act as stress signals that decreases cytokinin content, thus, increase root growth by releasing the inhibition on lateral root formation. The ratio of auxin and cytokinin concentrations is thought to be important for the regulation of developmental steps for the complete formation of lateral roots. Ethylene, a plant hormone that is involved in root response to stress, can either enhance or repress root growth, depending on its concentration. Lateral root formation and the relative growth rate of roots are stimulated by nitrate, ammonium, and phosphate, such that highly branched roots and greater root length density are found in enriched soil patches (Hodge, 2004). For immobile ions like phosphate, or poorly mobile ions such as ammonium, local root proliferation is important to increase nutrient exploitation from such patches. In contrast, a mobile ion such as nitrate may be more likely captured by a root system with a more extensive growth (i.e., explorative roots with small root branching density). Plant hormones and other biomolecules clearly have important effects on root branching and growth and the complexity of their interactions continue to be discovered.

According to a development-based classification scheme, root systems are composed of seminal roots that originate as part of the developing embryo in the seed (from only one seminal root in most eudicots to several in monocots), postembryonic shoot-borne roots (or adventitious, crown, or nodal roots), and lateral roots that emerge from all root types. In monocotyledonous plants, such as grasses, seminal roots grow out of the developing embryo, while shoot-borne roots subsequently arise from the shoot, and gradually replace the seminal axes. In contrast, in dicotyledonous plants, the entire root system originates from a single root in the embryo, from which laterals arise, and later can become a taproot, or thicken and become woody due to cambial activity. Numerous structures and entities comprise whole-plant root systems. Key entities of roots and their main functions are discussed here, but we refer the reader to Box 1 of Freschet et al. (2021a) for a more comprehensive list.

Root hairs are extensions of epidermal cells (i.e., trichoblasts) originating from the differentiation zone of root tips and vary in length from 0.2 to 2 mm depending on the species. By increasing the effective radius of the root, root hairs improve the acquisition of relatively mobile (e.g., nitrate) and immobile nutrients (e.g., phosphate) as well as water. Given an inverse relationship between root hair and mycorrhizal abundance, root hairs are thought to serve similar roles in resource acquisition as mycorrhizal hyphae. In addition, root hairs influence the formation of rhizospheres (i.e., soil being influenced by roots) and rhizosheaths (i.e., soil particles adhered to roots) to further regulate interactions among roots and their environments (York et al., 2016). Associated processes such as nutrient absorption kinetics, root exudates, and microbial activity in the rhizosphere affect nutrient availability and therefore plant uptake of nutrients from the soil.

Numerous other structures and unique root types are associated with specific functions. Mycorrhizal roots and root nodules are essential to plant-fungi and plant-bacteria associations, which are key drivers of resource acquisition (Bergmann et al., 2020; Tedersoo, 2017). Rhizomes, stolons, and tubers, which are not truly root structures but rather underground stems, along with true root clonal structures (i.e., root spacers) allow plants to spread clonally and regrow after disturbances (Klimešová et al., 2019). Sinker roots, buttress, and stilt roots are adapted for increased anchorage and support.

Root classification methods use the branching of root systems to describe and compare roots among and within species (Fig. 2). To classify roots using these methods roots or root segments can be counted starting from the outermost (i.e., distal) roots increasing counts inward (e.g., functional, morphometric, stream-order, centripetal or topological link-based approaches) or starting from basal (i.e., proximal) roots increasing counts outward (e.g., the developmental or centrifugal approach). Morphometric approaches are useful in situations where extracting whole root systems is challenging (e.g., woody or perennial species) and allows for functional classification of root orders, whereas the developmental approach is used to characterize whole root systems.

Fig. 2 Schematic presentations of systematic root classification approaches. (a) Developmental approach; (b) morphometric approach; and (c) topological approach. Root growth axis (a) and root order (b, c) levels are indicated by adjacent numbers; note that highest root orders are 5, 4 and 32, respectively (a–c), corresponding to 6, 4 and 12 classification levels (a–c). The ‘0’ root order in (a) can be replaced by root class (e.g., basal root, tap root); lower root order in (b) can be refined further, for example by adding information on the mycorrhizal status; the highest order number in (c) represents the numbers of root tips. Figure and caption from Freschet GT, Pagés L, Iversen CM et al. (2021) A starting guide to root ecology: Strengthening ecological concepts and standardizing root classification, sampling, processing and trait measurements. *New Phytologist* **232**: 973–1122. doi: 10.1111/nph.17572.

Roots can also be classified based on diameter classes, but diameter-based classification is now recognized as creating difficulties for distinguishing functional categories needed for many studies. Under diameter-based classification, roots of shared diameter classes are assumed to share specific functions, but roots of similar diameters can have entirely different functions among different species. It is often useful or desirable to separate portions of root systems associated with soil resource acquisition from the portion associated with providing structural support or transport. Although the entire root system in herbaceous plants can function for soil resource acquisition, typically the most distal two orders and a portion of the third order roots typically remain non-woody in woody plants and function as absorptive roots, while higher order roots undergo secondary development and function as structural or transport roots.

Trade-offs in root traits

Trade-offs in root traits can result from individual plant responses to environmental conditions or from selective pressures across generations. The resulting root traits are often optimized to balance resource limitation belowground with light limitation aboveground and to ultimately enhance growth, survival, or fitness. Most simply, the balanced growth hypothesis suggests that total plant growth will be largest when the root system maximizes nutrient and water acquisition per unit resource supplied by the shoot. However, allocation of large amounts of carbohydrates and nutrients to roots may detract from shoot growth, leaf area, and photosynthetic carbon gain, thereby reducing total plant growth, especially if the increased root allocation does not achieve increased rates of nutrient uptake.

Research over the last several decades has identified key trade-offs in aboveground plant form and function associated with fast growth and rapid resource acquisition versus slow growth and longevity. Key trade-offs associated with belowground resource acquisition, root tissue construction, extensiveness of root foraging (amount of root length in soil) and root collaboration with mycorrhizal fungal partners have been identified (Comas et al., 2012; Bergmann et al., 2020; Weigelt et al., 2021). A major gradient termed the “collaboration gradient” opposes “do-it-yourself” plants that have long specific root length and independently acquire resources with “outsourcing” plants that have large root diameters and cortical fractions, which support mycorrhizal associations (Fig. 3). A second major axis mirrors the aboveground “fast-slow” gradient such that one end of the gradient is characterized by root traits that promote high metabolic activity and rapid resource acquisition (e.g., large root nitrogen concentration) and the other end of the gradient is characterized by traits that promote longevity and survival of tissues (e.g., large root tissue density). Correlations between specific root length and root length density have also been identified (Comas et al., 2012), as has an independent axis of rooting depth (Weigelt et al., 2021). However, because data for traits associated with these axes are more limited, the strength and ubiquity of these patterns remain inconclusive. These recent findings have clarified our understanding of belowground trade-offs but further elucidating how plants allocate resources and adjust growth and morphology to optimize the capture of both above and belowground resources is necessary to further advance understanding of whole-plant trait integration.

Plants need to balance above versus belowground investments because acquisition of carbon via light capture and photosynthesis depends on acquisition of nutrients and water belowground, and vice versa. Aboveground, plants often adjust leaf

Fig. 3 Conceptual framework of the root economics space depicting (i) a collaboration gradient ranging from do-it-yourself soil exploration using large specific root length (SRL) to outsourcing by investing carbon into a mycorrhizal partner and hence into extraradical hyphae, which requires a large cortex fraction (CF) and root diameter (D) and (ii) a conservation gradient ranging from roots with high root tissue density (RTD) that show a slow resource return on investment but are long-lived and well-protected, to fast roots with a large nitrogen content (N) and metabolic rate for fast resource return on investment but a short life span. Arrows indicate negative correlations between the single traits. Figure and caption from Bergmann J, Weigelt A, van Der Plas F et al. (2020) The fungal collaboration gradient dominates economics space in plants. *Science Advances* 6: eaba3756. doi: 10.1126/sciadv.aba3756.

morphology (e.g., increase specific leaf area), allocation, physiology, or architecture in response to light limitation. Similarly, belowground, root traits and spatial distribution shifts in response to soil resource limitation, with plasticity in allocation and physiology being most critical for improving resource acquisition (Freschet et al., 2018).

Root traits for stress tolerance

Plants cope with abiotic stresses such as drought, nutrient limitation and imbalances, soil compaction, salinity, acid soil, heavy metal toxicity, and waterlogging via various mechanisms and adaptations (Koevoets et al., 2016). Plants must also maintain growth and survive in the face of biotic stresses such as competition, herbivory, and pathogens. Some plant species show highly specific responses and adaptations to stressors, many of which are moderated by root growth, architecture, traits, and physiological mechanisms.

Root systems and root traits are key components of plant strategies for coping with drought. Many drought-resistant plants avoid the negative consequences of moisture stress by optimizing water capture. For example, plants with deep root systems can access water from deep soil layers, and capture water that would otherwise percolate down and be lost from the system. Roots can exploit deep moisture via hydraulic lift, whereby deep moisture is transferred at night through passive physical processes to upper soil layers. Greater root length density and nutrient concentrations in upper soil layers make water and nutrient uptake possible during the following day.

Traits that effectively increase root contact with soil to improve hydraulic continuity have been shown to improve crop performance under drought (Comas et al., 2014). These include thin fine root diameters, long specific root length, high root length densities (especially in layers where soil moisture is greatest), large numbers of root hairs, root tips, and deep roots. Research suggests that many of these traits are regulated by specific genes and breeding for improved production of crops under drought stress is a promising avenue for agricultural research and practice (Comas et al., 2014; Li et al., 2021). Similar root characteristics are likely responsible for promoting plant growth under moderate moisture deficit, particularly in species with short life cycles, short growing seasons, or those species that use pulses of moisture for growth and survival, such as in monsoonal climates.

Numerous root traits are involved with drought tolerant plants strategies, i.e., the ability of plants to maintain low hydration and survive drought. Plants with large root tissue density have been shown to improve survival of perennial grass species in some Mediterranean systems and deep roots have been shown to improve seedling survival in annual systems. Root anatomical traits are also emerging as important drivers of drought-coping strategies in plants. For example, ratios of root tissues (i.e., aerenchyma, cortex, stele or xylem) explain adaptations of grass species to moisture gradients such that small cortex to stele and xylem to stele ratios, or large aerenchyma to stele ratios are advantageous in limited moisture conditions (Fig. 4; Yamauchi et al., 2020). Aerenchyma in extremely dry soil may provide a gap to limit water loss from roots back to the soil. The presence of storage organs and bud banks on belowground roots and stems is also of importance for regrowth of aboveground parts after senescence during a drought period. Despite these recent clarifications about how root characteristics influence drought tolerance, few studies, particularly from non-crop species, focus on root anatomical and physiological mechanisms of drought tolerance. Given that root anatomy governs hydraulic function of roots, further research in this area is needed to understand fully how roots and their functions influence plant performance in response to limited soil moisture.

As in aboveground responses to drought, root growth in response to moisture stress is regulated in large part by hormonal cues. Roots in contact with dry soil can be the source of inhibitors of shoot growth and stomatal opening, which in turn, limits water loss from the plant. Hydraulic signals that elicit physiological responses to drought move from the roots to the shoots in the transpiration stream, and the hormone abscisic acid (ABA), root-derived cytokinins, brassinosteroids, and ethylene phytohormones play a role in this signaling process (Gupta et al., 2020). The accumulation of ABA in roots and aboveground tissues activates signaling of various hormonal pathways and modulates the expression of many genes and physiological processes that protect cells

Fig. 4 Adaptive anatomical root traits for the soil water gradients, as predicted by the models of cortex to stele ratio (CSR) (a), xylem to stele ratio (XSR) (b) and aerenchyma to cortex ratio (ACR) (c). The xylem to whole root ratio (XWR) and aerenchyma to whole root ratio (AWR) were calculated by using the values of the CSR and XSR, and CSR and ACR, respectively. Figure and caption from Yamauchi T, Pedersen O, Nakazono M, Tsutsumi N (2020) Key root traits of Poaceae for adaptation to soil water gradients. *New Phytologist* 6(229): 3133–3140. doi: 10.1111/nph.17093.

Fig. 5 Schematic presentation of the movement of elements to the root surface of soil-grown plants. (1) Root interception: soil volume displaced by roots. from excessive water loss. ABA is also involved in hydrotropism, or a root's ability to sense and respond to water potential gradients in soil. Because of its key role in regulating plant responses to drought, the ABA pathway is a key target of many schemes aimed at improving water use efficiency and drought resistance in plants.

Nutrient limitations are well known to alter root growth in ways that increase the capacity of the root system to take up nutrients. Nutrient bioavailability is mediated by root interception, mass flow, and diffusion (Fig. 5; Marschner and Rengel, 2012). As roots grow, they displace soil and intercept available nutrients, for example, adsorbed onto soil particles. This process of root interception, however, is thought to provide only a small proportion of the plant's total nutrient uptake with mass flow, the transfer of water and dissolved nutrients to the root surface driven by water through the plant shoot via transpiration, typically accounting for a larger portion. Rates of diffusion, i.e., transport in soil along the concentration gradient, depend on the mobility and effective diffusion coefficients of specific ions, soil replenishment, and plant uptake. When transpiration rates are high and soil moisture adequate, large quantities of water and dissolved solutes travel to the root via mass flow, but as soils dry and mass flow of water is limited through large soil pores and channels, diffusion of nutrients from proximate soil may facilitate some plant uptake until soil moisture becomes further limited. When moisture is depleted from the soil matrix plant nutrient uptake also ceases.

Both mature and newer regions of the root can play a role in nutrient absorption. Even though older parts of the root system are more suberized and may be surrounded by depletion zones, they have been shown to have high potentials for nutrient uptake in laboratory experiments (Hawkins et al., 2014). Since they constitute a large proportion of the root surface area of the plant, they may be responsible for a considerable proportion of total nutrient uptake. However, the largest rates of nutrient uptake per unit root length are found in the region just behind the root apex, where root hairs are most abundant; more mature roots in older plants generally assume other primary functions (e.g., structural support).

Nutrient-poor soils elicit several changes in root morphology, as well as physiology, but the degree of these responses differs among plant taxa (Freschet et al., 2018). In addition, because individual nutrients have different movement and accumulation patterns in soils, limitations of specific nutrients are mediated via root systems in different ways. Some nutrients, such as phosphate and potassium, have limited mobility and thus accumulate in topsoil after litter decomposition. In contrast, more mobile nutrients such as nitrate and chloride are readily leached and thus accumulate in deeper soil layers. In phosphate limited soils, root growth tends to be concentrated in shallow layers, roots become thinner, and the elongation of laterals increases, especially those at the most distal orders, i.e., the finest, most absorptive roots. More numerous and longer root hairs are produced with faster elongation rates and the greatest benefit for absorption of ions that diffuse slowly in soil. In nitrate limited soils, larger concentrations of the nutrient may be found in deeper soil layers. Roots foraging for nitrate from deeper soil layers often results in greater root:shoot ratios. In addition, roots selectively proliferate in high-nitrate soil patches when nitrate distributions are heterogenous.

Compaction, like soil drying, increases the mechanical impedance to root penetration of soil, affects numerous root traits, and ultimately plant growth and fitness. Compaction increases bulk density, decreases soil porosity, and reduces water and nutrient availability. Because of these changes, compaction influences how and where roots grow. Plants with root systems that are susceptible to compaction will respond by producing lateral roots with shallow angles, and reducing total root length, number, and elongation rate. Plants with root systems more tolerant to compaction may increase root diameters, grow roots with higher tortuosity, and may grow many roots in available larger pore spaces (Correa et al., 2019). While growing through soil, roots must overcome radial, axial, and frictional forces, and there is typically a negative correlation between root elongation rate and penetrometer resistance (Bengough et al., 2011). The osmotic potential of root cells increases in impeded root tips, possibly as a mechanism to increase cell turgor and soil penetrability. Sloughing of the root cap as well as mucilage secretion may protect root meristems and reduce friction between roots and soil particles as they penetrate dense soils. Root impedance by mechanical forces in soil also triggers root signals that reduce leaf expansion and transpiration rates, also in part due to ABA signaling, and ethylene and auxin responses (Jacobsen et al., 2021). Reduced leaf expansive growth and shoot water loss induced by mechanical stress, even

under high nutrient and water supply, may prime plants growing in compacted soil for scarce availability of soil resources resulting from reduced root growth.

Salinity inhibits root elongation growth and development in non-halophytes, and this in turn, indirectly limits the ability of roots to explore soil for nutrients and water, which decreases the growth rate of the plant. Direct effects of salinity on roots include the osmotic stress and low soil water potential that can induce both the biosynthesis of costly organic osmolytes to regulate osmotic adjustment in the root, and the accumulation of specific ions in the root tissue, which can lead to induced toxicities and deficiencies. Salt tolerance is achieved by several potential mechanisms taking place in either shoots or roots. In roots, a ratio of low levels of Na^+ and high levels of K^+ in the cytoplasm can be achieved via selective ion uptake mechanisms or salt excretions, or both. Elevated Ca^{++} concentrations in the soil medium can increase the root elongation rate in some plant taxa in saline soils, possibly because there is less displacement of membrane-associated Ca^{++} by Na^+ than in less salt-tolerant genotypes.

Acid soils limit the availability of some nutrients, such as P, increase the availability and toxicity of heavy metals such as aluminium, and reduce colonization of roots by mycorrhizal fungi, all of which can reduce root growth. Aluminium toxicity decreases both root elongation and cell division, and root cells become shorter and wider giving roots a stubby appearance. The root tips are the primary sites of aluminium toxicity. In many tropical soils that experience low pH and aluminium toxicity, P is either deficient or is readily fixed to soil particles. Thus, the small root length density of plants in response to aluminium toxicity is an important limitation to P uptake and total plant growth. Other heavy metals, such as cadmium, copper, and zinc, also decrease root elongation, and root dry mass to a lesser extent, but the mechanisms for these responses are not clearly understood.

In waterlogged or flooded soils, air is displaced from soil pore spaces, and various degrees of oxygen depletion typically occur in heterogeneous microsites in the soil. Flooding of a previously well-aerated soil can cause immediate cessation of root growth, root respiration, and eventually root death if the lack of oxygenation persists. This is partly due to the production of toxic substances, such as nitrite, or acidification of the root cells due to lactic acid produced during anaerobic fermentation. In grass species adapted to restricted oxygen supply due to flooding, similar to those adapted to low soil moisture, plants tend to have high aerenchyma to stele area ratios and high cortical to stele area ratios for supporting aerenchyma but for different reasons (Fig. 4; Yamauchi et al., 2020). In waterlogged or flooded soils, these characteristics promote oxygen diffusion from the shoot base to root tips.

In some plant species after waterlogging, adventitious roots with well-developed aerenchyma, large air spaces in the root cortex, can emerge from the base of the stem, or existing roots can develop aerenchyma. The formation of aerenchyma under hypoxic conditions is associated with the production and accumulation of the plant hormone ethylene. Aerenchyma increases root porosity, and the long-distance transport of oxygen from the shoot base to apical zones of the root system. Pressurized gas transport, driven by temperature gradients between aboveground aerated parts of the plant and submerged root systems, also exists in some flooding tolerant species.

In addition to abiotic stressors, root systems are key components of plant responses to biotic stressors such as competition, herbivory, and pathogens. Research has linked root traits associated with a high level of root investment (e.g., greater root length density in soil, large root:shoot ratio and total root length) to competitive outcomes among plants, i.e., likely through increasing the ability of a plant to take up soil resources and negatively affect neighbor performance. Root traits also play an important role in defense against herbivory. Root derived toxins, traits associated with root toughness (e.g., structural macromolecules), and rhizosheaths are important components of belowground herbivore defense (Moore and Johnson, 2017).

Mycorrhizal symbioses are key to many plant root strategies and help plants overcome various types of stress (Latef et al., 2016; Tedersoo, 2017). Mycorrhizal colonization increases the surface area of the root system by extending hyphae beyond the root surface, and consequently increases nutrient uptake, especially of immobile ions in soil, e.g., phosphorus, zinc, and copper. Mycorrhizae increase the distance of nutrient exploration away from the root and are important in sites with patchy nutrient distributions. Water uptake is also increased for some plant species via mycorrhizae. There are two broad types of mycorrhizal associations. Arbuscular mycorrhizae (AM) are endophytes with intracellular colonization by Zygomycete fungi, whereas ectomycorrhizae (EcM) are endophytes with extracellular colonization by either Ascomycete or Basidiomycete fungi that form a mantle or sheath enclosing the tip of the rootlet. Dependence on AM tends to be greatest in plants with thicker diameter roots and large cortical areas that can host fungal partners. Many herbaceous species with extensive root length density in soil, long specific root length, and thin roots are facultative mycotrophs that show less colonization with increased phosphorus availability. For EcM roots, the bulky tissue of the mycorrhizal mantle surrounding the root tips serves a role in nutrient storage and in root-fungus contact but does not greatly increase the surface area for nutrient uptake. Instead, the extraradical mycelium that extends from the mantle and their rhizomorphs, conglomerations of hyphae with distinct structural shapes, perform this function. Ectomycorrhizal fungi exude hormones such as ethylene and auxin that stimulate root proliferation and branching for increased fungal colonization (Tedersoo, 2017). Both AM and EcM colonization frequently result in allocation of a smaller proportion of total plant weight to root dry weight. Additionally, most EcM fungi can produce exoenzymes capable of degrading soil organic matter and increasing organic nutrients, whereas this ability is generally absent from AM fungi that primarily acquire inorganic nutrients mobilized by soil saprotrophs. Consequently, EcM associations are more prevalent in nutrient-poor organic soils, whereas AM associations are generally found in relatively more fertile soils.

Genetic analysis of root traits

As with many aspects of plant growth and development, root architectural and morphological traits are usually under the control of a complex gene system in which several genes, rather than a single gene, operate together to create a given phenotype. Multi-gene

control of root traits and root responses make the study of root genetics difficult. Also, roots are hard to study due to the large numbers of plants needed for genetic studies, especially plants grown in soil under field conditions where phenotypic evaluation is most valid.

Methods in quantitative genetics and genomics such as quantitative trait locus (QTL) analysis, next-generation sequencing, and high throughput genotyping have allowed identification of the genetic underpinnings of root architecture and many root traits. New sensing and quantification approaches are being used in rapidly screening multi-dimensional phenotypes at cellular, organ, plant, and population levels to further advance understanding of how phenotypes with specific genes interact with environments (i.e., phenomics). In addition, molecular phenotyping approaches (e.g., transcriptomics, proteomics, metabolomics, and ionomics) provide information about trait inheritance in relation to plant physiology.

QTL associated with enhanced drought performance have been identified in numerous crop species (Siddiqui et al., 2020; Ye et al., 2018). These include QTL linked to rooting depth, root length density, root number, root hairs, root angles, and root xylem. Some of these traits are likely associated with stable QTL and have also been shown to be heritable, indicating that breeding for them is a promising avenue for improved plant performance in diverse agroecosystems. Single-gene traits for root morphological traits have been identified in some plants but are most often studied in a tiny crucifer, *Arabidopsis thaliana*, a model species used by plant geneticists. Mutants for traits such as failure to initiate lateral roots, auxin-related lateral root growth, and variable lateral root initiation in response to the soil environment exist in this species. Transgenic *Arabidopsis* plants have also been used to demonstrate the function of a specific gene controlling the proliferation of lateral roots in nitrate-rich patches. In normal, non-transgenic plants, the expression of this gene is induced rapidly when nitrate is supplied, but in transgenic plants in which the gene is repressed, roots no longer proliferate in response to nitrate. The gene is therefore a key factor in determining the developmental plasticity of roots in response to an environmental cue. Specific genes associated with high investment in roots, rooting depth, and root crown angle have also been identified in wheat, maize, and rice varieties (e.g., Jung and McCouch, 2013).

The strong effect of the abiotic and biotic environment in the soil on root development and branching patterns is important for understanding the inheritance of root traits and their adaptation to specific habitats. For many crops, extensive genotypic variation exists for root system traits among cultivars, and research continues to unravel the genetic basis of these traits for improved breeding. Integration of genes from wild varieties related to plant responses to various stresses such as drought can further improve plant performance for more sustainable use of water and nutrients. The editing of genomes using the clustered regularly interspaced short palindromic repeat (CRISPR) technology is being developed to enhance drought tolerance, yield, and domestication, and root traits influencing these characteristics.

Root trait effects on plant communities and ecosystem processes

Plants shape and alter ecosystems and associated properties and processes through their interactions with one another, with other organisms, and with the environments in which they grow. Root systems and their traits are critical components of these interactions and key drivers of ecosystem functions including productivity, carbon cycling and sequestration, nutrient cycling, water budgets and hydraulic redistribution, and soil aggregation and stability (Fig. 6) (Bardgett et al., 2014; Freschet et al., 2021b).

Recent estimates suggest that approximately one quarter of standing plant biomass exists belowground with the largest ratios between below and aboveground fractions found in grasslands (c. 65%), followed by shrublands (c. 50%) and forests (c. 20%). This belowground biomass contributes substantially to overall plant productivity and carbon sequestration. However, these estimates also vary within each of these ecosystems globally and are differentially impacted by root turnover rates in different ecosystems. For example, ecosystems with high mean annual temperatures tend to have greater turnover rates, such that standing biomass underrepresents total biomass produced more so in these regions. Root biomass, surface area, and distribution through the soil profile are particularly important for measures of fine root productivity and carbon cycling due to their relatively short lifespan, small C:N ratio, which enhances turnover rates, and their role in nutrient absorption, and, thus, net primary production. Various root traits affect carbon in ecosystems by modifying carbon inputs, losses, transformations, and retention in soil. Root traits associated with decelerated cycling of carbon include symbiosis with ectomycorrhizal fungi, slow root turnover rates, and long root lifespans. Roots with low specific root length, small N:C ratio and high lignin concentrations tend to have longer lifespans and slower rates of decomposition. Root respiration and exudation alter carbon storage in soil via their effects on CO₂ flux. Roots also promote specific microbial communities that further alter carbon dynamics with fungal communities tending to sequester more carbon than communities dominated by bacteria.

Spatial and temporal patterns of changes in root growth, architecture, and distribution, among other traits, affect nutrient availability in soil, as well as retention and loss of these resources to the atmosphere, runoff, and leaching. As described earlier, the distribution of roots in response to nutrient availability in different soil layers affects nutrient acquisition throughout the soil profile. In addition, numerous root traits are associated with increased or decreased nitrogen and phosphorus inputs into soils. Roots with large nitrogen concentrations show positive correlations with nitrogen mineralization, nitrification, and negative relationships to nitrogen immobilization. Root associations with mycorrhizas also influence nutrient cycling such that communities dominated by AM fungi primarily utilize inorganic nitrogen forms and have overall faster nitrogen cycling rates, whereas those dominated by EcM fungi are capable of using more complex forms of nitrogen and have slower rates of nutrient cycling. Root phosphorus concentrations can also be key drivers of phosphorus inputs in soils via litter shedding and root turnover, especially in phosphorus limited systems. The solubilization of phosphorus from bedrock by deep roots and associated mycorrhizal fungi is also

Fig. 6 Categories of root traits that have potential to impact ecosystem processes, including architectural, morphological, physiological, and biotic traits. The general idea behind a trait-based framework is that variation in root traits across individual plant species, communities, and ecosystems captures variation in a range of ecosystem processes, including carbon and nutrient cycling, and the structural stability of soil. Images represent the different root trait categories with potential to impact ecosystem processes: (A) root systems of *Leucanthemum vulgare* growing on agar plates by Liesje Mommer, Wageningen University (WU), representing architectural traits; (B) cross section of root of *L. vulgare* stained toluidine blue by Eric Visser, Radboud University, Nijmegen; (C) root length scan of washed roots from diverse grassland community by Natalie Oram (WU), both representing morphological traits; (D) root nodule in *Medicago truncatula* by Erik Limpens (WU); (E) arbuscules of AM fungi in *M. truncatula* root by Rik Huiskes (WU), both representing biotic traits; and, finally (F) rhizodeposition around *Zea mays* root by Davey Jones, Bangor University, representing physiological traits. Figure and caption from Bardgett RD, Mommer L, De Vries FT et al. (2014) Going underground: Root traits as drivers of ecosystem processes. *Trends in Ecology and Evolution* **29** (12): 692–699. doi: 10.1016/j.tree.2014.10.

a major source of phosphorus uplift to the topsoil horizon, which explains the retrogression of very old ecosystems progressively disconnected from bedrock as soils grow thicker and bedrock becomes inaccessible to roots (Peltzer et al., 2010).

Root architecture and traits influence relationships among plants and water budgets and cycling at both small and large scales. Competition between plants in the same community affects root distribution and water uptake. Studies that use isotopic techniques along with measurements of root biomass and leaf gas exchange provide an assessment of root distribution, short- and long-term physiological activity, and source water use to inform competitive interactions. In tree-grass mixtures, for example, grasses exert a negative effect on tree root growth, but usually not vice versa. Drought, however, typically has a more negative effect on grass than on trees, which have more conservative leaf gas exchange characteristics, and deeper roots that utilize deeply stored water. As previously mentioned, plants with deeper roots, such as trees, can further redistribute water from the deep soil to the shallow soil horizons overnight, a process called hydraulic lift or redistribution which also benefits more shallow rooted species. Isotopic techniques as well as experimental and observational studies continue to sort out these complex, root-mediated, competitive relationships. Root traits may also influence competitive dynamics between native and invasive species. For example, rapid root growth of the invasive annual grass, *Bromus tectorum*, in cool conditions allows it to pre-empt resources and outcompete co-occurring native grass species, whereas root traits such as large numbers of root tips and large root to shoot ratios have been shown to improve native plant performance in response to competition from invasives *B. tectorum* and *Centaurea stoebe*.

At a regional scale, root distribution can affect hydrology. An example is the replacement of perennial, deep-rooted (~20 m) trees and shrubs, by shallow-rooted pasture and crop plants in the seasonally-dry Murray-Darling Basin in Australia. Historically, the native vegetation would have relied on deep soil recharge and groundwater, while the shallow-rooted agroecosystems today occupy only the top meter of soil and utilize far less water than the forest and woodland communities, whose evergreen canopies had higher evapotranspiration rates.

Many aspects of soil structural stability (Bardgett et al., 2014; Rillig et al., 2015) and slope stability (Stokes et al., 2009) are altered by root systems and specific root traits. Roots promote the formation and stabilization of soil aggregates by compressing or entangling soil particles, by providing food sources (e.g., organic residues from roots sloughing or dieback) for microbes that secrete organic polymers or directly via their root exudates, both of which bind together soil particles. Roots mitigate soil detachment and erosion by enhancing soil cohesion (a component of soil shear strength) and aggregate stability (i.e., the ability to resist disintegration under force). As roots extend through soil vertically and laterally, they reinforce soil to increase its shear strength and overall soil cohesion. The distribution of roots, their length, orientation, and tensile strength (i.e., the force required to break a root divided by the cross-sectional area of a root) also influence soil and slope stability.

Conclusion

Research focused on root form and function has improved understanding of the mechanisms by which plants cope with environmental stress, the dynamics of plant-plant and plant-microbe interactions, and how roots influence various ecosystem processes, properties, and services. Despite significant advances, additional research is needed to understand how root growth and traits influence plant performance, vegetation dynamics, and associated ecosystem processes in changing conditions. Increased focus belowground on dynamic plant traits (e.g., turnover rates, root lifespan), regenerative traits (e.g., belowground bud bank size and storage), anatomical traits (e.g., cortex and stele area ratio), and physiological traits (e.g., hydraulic conductance) are areas where knowledge remains particularly scarce. In addition, a more comprehensive understanding of between- and within-species variation in root growth and traits may improve our ability to select plants with specific traits for increased crop productivity and improved restoration in the face of various global change pressures. Luckily, methods for root trait sampling, processing, and measuring are continuously being improved and refined to ensure consistency across studies and ecosystems (Freschet et al., 2021a, 2021b). In addition, as data accumulate from diverse systems and become available via large databases (e.g., Global root database, Guerrero-Ramirez et al., 2021) researchers will be able to further clarify linkages between root traits and vegetation dynamics across diverse ecosystems and scales.

Abstract

Root mucilage is a sticky polymer that is secreted through root border cells. Primarily composed of polysaccharides, with some protein and lipid components, mucilage causes soil particles to adhere to the roots, creating the characteristic rhizosheath that is visible around many plant root systems. The mucilage layer retains water, which is important for plants growing in water-limited environments. Plant signal molecules are transmitted through the mucilage to symbiotic and free-living soil microorganisms that promote plant growth. Furthermore, mucilage contains defensive compounds that can prevent infection by root pathogens. This chapter discusses multiple functions of root mucilage for plant health and resilience.

Key points

- Root mucilage is a complex mixture of polysaccharides, proteins and lipids, secreted by plants in response to genetic and environmental factors.
- Mucilage creates an adhesion between roots and soil particles, bringing roots into closer proximity to the soil water and dissolved nutritive ions.
- Mucilage retains water when soils become drier, creating a humid microenvironment that attracts soil microorganisms, assembling the rhizobiome.
- Root mucilage protects plants from pathogens. Mucilage is a physical barrier between soil-borne pathogens and the root surface, and it contains extracellular DNA, histone and other antimicrobial compounds that halt disease-causing microorganisms before they can infect the plant.

Introduction

The rhizosphere is the unique soil microenvironment that exists around growing plant roots (Fig. 1). The rhizoplane is the most dynamic zone of the rhizosphere. Located at the interface between the external root surface and the soil particles surrounding the root, the rhizoplane is enriched with plant root secretions and debris called rhizodeposits (Fig. 1). Rhizodeposits include the abraded root cap and border cells, dead root cells, water-soluble root exudates, respired gasses and mucilage. The mucilage released from roots, combined with root hairs, is responsible for the formation of a rhizosheath, the mass of soil adhering to plant roots that does not fall away when roots are gently shaken.

The rhizosheath forms because mucilage is an adhesive substance that causes soil particles to stick together, creating porous soil aggregates near the root surface. The rhizosheath protects plants from desiccation in dry and semi-arid environments, for two reasons. First, mucilage has a polymeric gel-like structure that attracts and retains water molecules. Second, porous soil aggregates hold water under tension, which prevents the water from draining out of the rhizosphere. Another feature of soil aggregates is that they contain clay, which has a large surface area occupied by exchangeable ions such as Ca^{2+} , Mg^{2+} , NH_4^+ and K^+ , essential plant

Fig. 1 Plant rhizosphere, showing the various components of the root system, secretions and surrounding soil. Mucilage is a polysaccharide-rich compound that is produced in border cells in the plant root tip. Photos show (a) mucilage being released from the brace root tip of corn (*Zea mays*) at the reproductive stage, and (b) mucilage secreted from the fine root tips of 3-day old wheat (*Triticum aestivum*) seedlings. Photos from Holz M, Leue M, Ahmed MA, Benard P, Gerke HH and Carminati A (2018) Spatial distribution of mucilage in the rhizosphere measured with infrared spectroscopy. *Frontiers in Environmental Science* 6: 87. doi: 10.3389/fenvs.2018.00087.

nutrients. The presence of nutrient-rich clays in the rhizosheath reduces the distance that ions must diffuse to reach the root surface, where they are absorbed by the plant. Furthermore, porous soil aggregates are a microhabitat for root symbionts, endophytes and free-living microorganisms that help plants to acquire water and nutrients.

The rhizosheath was first described in desert grasses, as a sheath of agglutinated sand particles around the roots (Price, 1911). Plants with a visible rhizosheath secrete mucilage and have additional characteristics that favor the root-soil adhesion, such as their root hair length, density, morphology and a diverse root microbiome. Mucilage secretions can account for nearly half of the rhizodeposits from grasses. Root mucilage is a viscous, gel-like material. It is composed of polysaccharides (~78%), glycoproteins (~7%), minerals (~6%) and lipids (~3%) (Nazari, 2021). Most plant mucilage is produced in the Golgi apparatus and it is released predominantly from fine root tips, which extend from the distal tips of the lateral roots into the surrounding soil. The rhizosheath forms because the gelatinous mucilage layer around border cells, outside of the fine root tip, adheres strongly to the surrounding soil particles by hydrogen bonds between the hydroxyl groups of the polysaccharides and soil particles (Watt et al., 1993). Mucilage lubricates growing roots as they extend into soil pores and coats the surrounding soil particles to protect the delicate root tip from abrasion.

Mucilage varies in its chemical composition, and this affects its functions in different plant species (Table 1). For example, some organic molecules like pectins and arabinogalactan protein have bioadhesive properties, meaning that they bind microbial cells to the root surface. Mucilage molecules like xyloglucan are responsible for soil adhesion because they act as a glue between the root surface and soil particles (Table 1). Other functional molecules in mucilage are responsible for stress response, pathogen control, cation exchange and hydraulic properties at the root-soil interface (Table 1). Enzymatic degradation of polysaccharides present in mucilage could provide carbon substrates that are metabolized by growing soil microorganisms. Therefore, root mucilage contains diverse compounds that support many physical, chemical and biological processes around roots.

Production and chemistry of root mucilage

Most plant roots are coated with mucilage, but the root tip has the thickest mucilage layer. This is because mucilage at the root tip adheres to cellular debris (sloughed border cells) that are scraped off the root as it grows (Fig. 2a). The thick mucilage layer protects the root apical meristem as the growing root tip penetrates pores, cracks and voids in the soil matrix. Biosynthesis and production of mucilage occurs mainly in root epidermal cells. As illustrated in Fig. 2b, mucilage is produced in the Golgi apparatus inside the cells of the root apical meristem, then transferred into the cytoplasm via the cisternae, the flattened membrane vesicles within the Golgi apparatus. Mucilage is stored temporarily in the cisternae, mixed with aqueous solution and moved through the outgoing transport vesicles. These vesicles traverse the cytoplasm and fuse to the meristematic cell membrane, where their contents are discharged into the periplasm as mucilage droplets. Finally, mucilage droplets are secreted through pores in the meristematic cell wall, onto the surface of the root epidermal cells and form a gelatinous layer that adheres to the surrounding soil (Fig. 2).

Early studies of root mucilage relied upon visual images of stained root cross-sections, viewed with light microscopy. Soaking root extracts in acid-Schiff reagent with methylene blue dye proved that mucilage contains carbohydrates with cis hydroxyl groups. Ruthenium red dye binds to pectins in mucilage. Lipids in mucilage are visible under a light microscope when triglycerides react

Table 1 Mucilage components found on the root surface of representative plant species, and their functions.

Fig. 2 Production and secretion of mucilage from root tip cells. At the root tip, (a) the epidermal cells are coated with a mucilaginous layer. Mucilage biosynthesis occurs in (b) the Golgi apparatus of a meristematic cell, producing mucilage droplets that travel through the cytoplasm. In the periplasmic space, (c) root exudates are encapsulated within the mucilage droplets, and these compounds move jointly through the cell wall before they are deposited in the mucilage layer. The root exudates diffuse gradually through the mucilage layer into the adhering soil, which is inhabited by free-living soil bacteria and fungi. Adapted from Driouch A, Gaudry A, Pawlak B and Moore JP (2021) Root cap-derived cells and mucilage: A protective network at the root tip. *Protoplasma* **258**: 1179–1185. doi: 10.1007/s00709-021-01660-y; Silva J, Ferraz R, Dupree P, Showalter AM and Coimbra S (2020) Three decades of advances in arabinogalactan-protein biosynthesis. *Frontiers in Plant Science* **11**: 610377. doi: 10.3389/fpls.2020.610377.

with fat-soluble Sudan III red dye. These visual observations led to a mucilage classification scheme, which distinguished the cellulose-based mucilage (containing cellulose microfibrils) from the amorphous pectin-based mucilage.

Today, the complex chemistry of root mucilage and its physical functions are studied with advanced chemical techniques like gas chromatography-mass spectrometry, ^1H and ^{13}C nuclear magnetic resonance spectroscopy, and Fourier-transform infrared spectroscopy. Analysis of the cellulosic polysaccharides in mucilage, such as xyloglucan and heteromannan, showed that these compounds create stability and cohesion in mucilage polymers. Mucilage hydration is maintained by pectic polysaccharides, namely homogalacturonan, rhamnogalacturonan-I, and xylogalacturonan. In some cases, the cellulose and pectin components of mucilage bind together to create an extensive polymeric network. Mucilage also contains cell wall glycoproteins like arabinogalactan proteins and extensins that protect the integrity of root cells beneath the mucilage layer.

Mucilage has multiple functions that are beneficial to plants. Mucilage forms the rhizosheath, which brings nutrient-rich clay particles close to the root surface, allowing for ion exchange and interception by growing roots. Mucilage protects elongating root tips from abrasion. The polymeric, gel-like structure of mucilage retains water in the rhizosphere. Soil ions and water pass through the mucilage layer to reach the root surface, but substances also flow in the other direction, from the roots into the mucilage layer and then into the surrounding soil. Many low molecular weight root exudates move through the mucilage layer into soil, including tannins, alkaloids, steroids, polyphenols, terpenes, flavonoids, phenolic acids and anthocyanins. As illustrated in Fig. 2c, root exudates are transported out of root cells through active and passive transport, then discharged into the periplasm along with mucilage droplets. Root exudates that become encapsulated in mucilage droplets are secreted together through cell wall pores, into the mucilage layer on the external surface of the root epidermal cell. This is how root exudates reach soil microorganisms in the rhizosheath and surrounding soil (Fig. 2c).

Root exudates are often described as a source of energy and carbon for soil microbial populations, but they have other functions. Some root exudates like flavonoids and strigolactones are signal molecules that stimulate microbial movement or growth towards the root. Attracting nitrogen-fixing bacteria, mycorrhizal fungi and other plant growth-promoting microorganisms (free-living and endophytic) to roots is expected to improve plant growth. However, signal molecules may also induce the growth of plant pathogenic fungi and parasitic nematodes that infect root tissues, an undesirable outcome. Some root exudates elicit microbial biosynthesis of secondary metabolites like phytohormones and siderophores in the rhizosheath. For example, the root exudate L-tryptophan is the catabolic precursor of the plant growth-stimulating hormone indole-3-acetic acid produced by rhizosphere bacteria (Kravchenko et al., 2004). Microbial byproducts may stimulate or inhibit plant growth, depending on the nature of the compound, the environmental conditions and the plant species involved. Mucilage seems to distribute root exudates where they are needed to enhance the connection between plant roots and soil microorganisms, thereby controlling plant-microbial interactions in the rhizosphere.

Factors affecting root mucilage production

Most angiosperms produce mucilage, but rhizosheath formation is more common in grasses and cereal crops in the Gramineae family. Well-developed rhizosheath is visible around the roots of cultivated cereals like corn (*Zea mays*), wheat (*Triticum aestivum*), barley (*Hordeum vulgare*), oat (*Avena sativa*) and sorghum (*Sorghum bicolor*) (Duell and Peacock, 1985). Since as much as 50% of the rhizodeposits from these cereal crops is allocated to mucilage production, which is equivalent to about 10% of the total carbon fixed through photosynthesis, this suggests a specialized growth strategy. We expect plant species to allocate more energy and carbon to mucilage production when exposed to abiotic stress (e.g., drought, heat, trace metals) or biotic stress from pathogens and parasites.

Abiotic stress and root mucilage

Drought occurs when there is insufficient rainfall or irrigation to replenish the soil water supply for plants. As the soil water content declines, plants must exert more hydraulic force to pull water under tension out of soil pores, to the root surface. Plants with an inadequate water supply must close their stomates to avoid desiccation from evapotranspiration, which limits photosynthesis. Since water is retained in the polymeric structure of mucilage and in porous soil aggregates adhering to the mucilage layer, plants may deliberately secrete mucilage to prevent root dehydration. Mucilage-producing plants that can attract mycorrhizal fungi to colonize their roots will have extra capacity to acquire water because fungal hyphae can extract water from soil micropores that are too small for plant roots to penetrate. There is evidence that plants release more mucilage in response to soil water shortage. For example, corn genotypes growing in semi-arid regions produce more mucilage than corn genotypes in humid regions (Table 2; Nazari et al., 2020). The amount of galactose, fructose, mannose, glucose, arabinose, xylose, and glucuronic acid contained in nodal root mucilage also vary among corn genotypes in different agroecological regions (Table 2). It is not fully understood why corn plants modify the proportions of polysaccharides in mucilage when they grow in a water-limited environment. It could be to optimize the water-holding capacity of mucilage, which depends upon the number of hydroxyl and carboxyl groups present in polysaccharides. Therefore, changes in the quantity of mucilage produced and its chemical composition could be a plant strategy to survive water shortages, although this remains to be confirmed.

Heat stress occurs when plants cannot regulate their internal temperature in hot environments. Heat stress limits plant root development, which could affect mucilage production and chemical composition. In corn plants, the root cap grows optimally at 25 °C, producing about 3600 cells d⁻¹, which is an order of magnitude greater than 360 cells d⁻¹ produced at 15 °C and four times more than 850 cells d⁻¹ produced at 35 °C (Clowes and Wadekar, 1988). A decline in root cell production at hotter temperatures will probably reduce the amount of mucilage produced around the root tip. Furthermore, extreme heat stress causes plants to close their stomates, which lowers their transpiration and photosynthesis rates. Less carbon fixation constrains many biosynthetic processes of plants, including mucilage production and is expected to alter the relative proportions of polysaccharides, proteins and lipids contained in mucilage.

Contaminants like trace metals affect root mucilage production, although the response depends on the metal ion and the exposure dose (i.e., from the smallest observed effect concentration to the lethal concentration). Root epidermal cells exposed to trace metals often experience reactive oxygen stress, which disrupts the cell membrane due to lipid peroxidation and impaired thiolation of proteins, decreases cellular respiration, impairs biochemical reactions and damages cellular DNA. Mucilage contains uronic acids and pectin molecules that bind to metal ions, thereby protecting root epidermal cells from reactive oxygen stress. When saltmarsh mallow (*Kosteletzkya pentacarpos*) was exposed to Zn²⁺ from 0.1 mM ZnCl₂ solution, root mucilage production increased from 12 to 18 mg g⁻¹ plant (dry mass), and the uronic acid concentration in mucilage rose from 50 to 180 µg mg⁻¹ of mucilage on a dry weight basis (Zhou et al., 2020). Plants vary the pectin content in mucilage when exposed to trace metals, possibly because

pectin is a selective binder of trace metals. For example, Cai et al. (2011) reported that soybean root tips exposed to Al^{3+} had a thicker mucilage layer and more pectin methylesterase activity, which was associated with proton release and Al^{3+} binding to pectin in the mucilage layer.

Biotic stress and root mucilage

Plant roots are exposed to biotic stress from viruses, pathogenic fungi and bacteria, soil nematodes and other biota, which activate plant defense mechanisms. Once a pathogen is detected, plants upregulate the phytohormone signaling pathways of salicylic acid, jasmonic acid, and ethylene that initiate pathogenesis-related peptides and genes, triggering the systemic acquired resistance defenses. However, plants can also rely on root mucilage for physical and chemical defense. Mucilage combined with the root cap-derived cells creates the mucilaginous root extracellular trap, a sticky adhesive that prevents pathogens from moving to and infecting the growing root tip. Once the pathogen is physically immobilized, it is deactivated by defensive molecules, including extracellular DNA, defensive peptides and proteins, contained in the mucilage. Mucilage fills xylem vessels in injured plant roots, which prevents pathogen invasion. For example, a wounded corn root produced mucilage with abundant pectin that filled 3 cm of xylem vessels in the injured area after 1 day, and this restricted pathogen infection of the damaged root tissues (Crews et al., 2003).

Plants in the Fabaceae family respond to signals from invading pathogens by releasing 'extracellular trapping' substances such as extracellular DNA and granular proteins (e.g., histone) from lysed border cells in their root mucilage. For example, pea roots released extracellular DNA from the border cells when exposed to the flagellin signal molecule of pathogenic *Ralstonia solanacearum* but did not respond to the presence of the *R. solanacearum* mutants that lack flagellin or the non-pathogenic bacteria *Pseudomonas aureofaciens*, *Ensifer meliloti* and *Escherichia coli* (Gunawardena and Hawes, 2002; Tran et al., 2016). This implies that root mucilage production is part of the defensive response to root pathogens. Mucilage may function as a physical barrier to root invasion, as discussed above. Another possibility is that extracellular DNA and other compounds in the mucilage bind to chemical receptors in the pathogen cell membrane to interfere with pathogen growth and root infection. The ability of pea roots to alter their mucilage production after detecting flagellin from a pathogen suggests that mucilage is responsible for specific defense mechanisms that prevent plant diseases.

Functions of root mucilage

Water retention

Mucilage is a gel-like, hygroscopic substance that can absorb water at a rate of 25–600 times its dry weight, due to its high hydroxyl content (Huang and Gutterman, 1999). For example, mucilage-treated soil maintained a volumetric water content of $0.24\text{--}0.25\text{ cm}^3\text{ cm}^{-3}$ when dried, but the soil water content without mucilage declined from $0.25\text{ cm}^3\text{ cm}^{-3}$ to $0.17\text{ cm}^3\text{ cm}^{-3}$ in 200 min (Kroener et al., 2014). When soil is moist, mucilage becomes hydrated and retains water around the rhizosheath. The presence of mucilage is expected to increase the volumetric water content of the rhizosheath by 3–5% at water potentials of -10 kPa , with about 2% more volumetric water in the rhizosheath at -10 MPa (Ahmed et al., 2014; Ghezzehei and Albalasmeh, 2015). Transpiration pulls water from deeper soil layers to the roots, and water is likely to be adsorbed onto or absorbed into the mucilage layer of the rhizosheath, due to the hygroscopic character of mucilage. When soils become drier, the long-chain lipids in mucilage create a temporary water repellent layer, which prevents water loss from the rhizosheath. Furthermore, mucilage is viscous, which enhances the physical contact among soil particles around the rhizosheath. Formation of soil aggregates allows for the development of a soil microstructure, with small pores that hold water more tightly than large pores. Mucilage acts as an adhesive between the root surface and soil aggregates, which improves the connectivity of water-filled soil pores and the rhizoplane. Cohesive water tends to remain longer in soil micropores, whereas it drains readily from soil meso- and macro-pores. Together, these mucilage-induced effects in the rhizosheath mean that the root surface remains moist, even as the surrounding soil gets drier.

Protective barrier

Root mucilage acts as a protective barrier for the root tips because hydrated mucilage is a lubricant. Growing roots exert tremendous pressure ($>700\text{ kPa}$) on root tips to push them through the soil (McNear Jr, 2013). The lubricating effect is due to the polysaccharides and lipids in mucilage. Effectively, these compounds reduce friction between the growing root tip and soil particles, so that the growing root tip can easily penetrate into the soil without being damaged.

Nutrient absorption

Since the mucilage layer around the rhizosheath is relatively well-hydrated, compared to the surrounding soil, it enhances nutrient uptake around the root. Most plant nutrients are acquired from dissolved ions in the soil pore water, which move from the bulk soil to the root surface through diffusion (e.g., H_2PO_4^- , K^+ , NH_4^+ , Zn^{2+}) and mass flow (e.g., Ca^{2+} , NO_3^-) processes. Thus, plant nutrient uptake is controlled by the amount of water that reaches the root, as well as the length of time the ion-rich water is in contact with the rhizosphere. The rhizosheath facilitates the transfer of dissolved ions to the root surface. For example, the rhizosheath improved the Zn absorption into oat roots by 40% in dry soil with $<1.5\text{ MPa}$ water potential (Nambiar, 1976). Acquisition of phosphate ions is enhanced by root mucilage, for two reasons. First, lipids (mainly phosphatidylcholines and saturated lipids) in root mucilage reduce the capillary force needed to mobilize H_2PO_4^- that is adsorbed onto soil particles through intermolecular cohesion and adhesion forces. This phenomenon can increase the phosphate ion concentration in soil solution by 10% (Read et al., 2003).

Second, the mucilage provides a moist layer around the roots that favors ion diffusion, increasing the likelihood that phosphate ions will enter the rhizosphere rather than remain in the bulk soil. Therefore, mucilage production is expected to increase plant nutrient uptake from soil.

Binding of trace metals

Mucilage is a negatively charged organic molecule with an abundance of carboxylic group (e.g., in uronic acid monomers) that can bind cations, including trace metals. Uronic acids in the mucilage of plants like Arabidopsis, cress (*Lepidium sativum*) and saltmarsh mallow (*Kosteletzkya virginica*) generally bind large amounts of Ca^{2+} but may exchange Ca^{2+} for other monovalent and divalent cations in the soil pore water, such as Na^+ , Pb^{2+} and Cd^{2+} (Ghanem et al., 2010). The cation exchange capacity of mucilage can enhance the transfer of such ions from soil water to the plant. For example, saltmarsh mallow grown in a Na^+ soil environment had a greater Na^+ concentration in the mucilage and shoot tissue, relative to the Ca^{2+} concentration, probably because Na^+ was bound preferentially to the uronic acid and rhamnose in mucilage (Ghanem et al., 2010). However, the plant family Melastomataceae produces mucilage with unmethylated uronic acid that has high affinity for trivalent cations, such as Al^{3+} . In a hydroponic experiment with melastoma (*Melastoma candidum*), plants that produced root mucilage accumulated 83% more Al^{3+} in the shoots than plants without mucilage (Watanabe et al., 2008). It is equally likely that Al^{3+} will remain bound in the mucilage, which is beneficial for plants that are sensitive to Al toxicity. For example, cowpea (*Vigna unguiculata*) produced mucilage that retained about 50% of the added Al^{3+} within 5 mm of the primary root tips, without transferring the Al into the root tip meristems (Horst et al., 1982). Given the capacity of root mucilage to retain cations, some excluder plants may produce uronic acid-rich mucilage to limit their exposure to non-essential cations like Na^+ , Al^{3+} and trace metals. This could be a metal tolerance mechanism to limit the contaminant uptake in plant tissues.

Rhizobiome: Mucilage-microorganism interaction

Mucilage and root-associated bacteria

Mucilage is expected to affect the growth and activity of microorganisms living in and around plant roots. There are several ways that mucilage attracts motile microorganisms to the root surface, and assembles a diverse microbial community known as the rhizobiome: (1) mucilage retains water, providing a moist microenvironment, (2) signal molecules diffuse through the mucilage, allowing for communication between plant roots and microorganisms in and around the rhizosphere, (3) some of the polysaccharides, lipids and proteins in mucilage are labile compounds that microorganisms metabolize for energy and use to build cellular components, as they grow and reproduce, (4) within the mucilage, polysaccharides with highly branched structure create a sticky, adhesive barrier that restrain microbial cells, including pathogens, from making direct contact with root cells, and (5) mucilage contains extracellular DNA that can control pathogen infections of the root.

Mucilage provides a moist microenvironment for the rhizobiome

All organisms need water to survive. Mucilage released from the root tips attracts microorganisms because it changes soil hydraulic properties in the rhizosphere (soil water content, water potential and saturated hydraulic conductivity). The moist conditions encourage hyphal growth and motile bacteria towards the root. Also, the passive movement of spores and non-motile bacteria into the rhizosphere is enhanced by the water-attracting properties of mucilage. In general, the moist mucilage-rich rhizosheath supports more microorganisms than bulk soil. There were 1×10^8 CFU g^{-1} of culturable bacteria in a grass (*Calamovilfa longifolia*) root rhizosheath, which was two orders of magnitude greater than the 3×10^6 CFU g^{-1} in bulk soil from a sand dune (Bergmann et al., 2009). Water that is held by mucilage in the rhizosheath may contain less oxygen and have fewer dissolved ions than the bulk soil, as these essential substances are either absorbed into the root or used by the actively-growing rhizobiome. This is expected to increase competition in the rhizobiome community, which will strive to acquire more nutrients to meet their requirements and continue growing, reproducing and colonizing the moist mucilage-rich coated roots and rhizosheath.

Mucilage transfers signals from plant roots to the rhizobiome

The rhizobiome contains soil microorganisms that are specially adapted to grow in the rhizosphere, as mutualists, commensals and parasites. Roots communicate with their rhizobiome by releasing chemical signals in root exudates. Plant signal molecules are generally low-molecular weight compounds like organic acids, sugar, aliphatic acids, fatty acids, amino acids, flavonoids, plant hormones and secondary metabolites. Plant signal molecules elicit a response from the rhizobiome. This could be a specific growth response that entices the microorganism towards the root, which occurs with root symbionts such as nitrogen-fixing bacteria and arbuscular mycorrhizal fungi. However, some plant signaling molecules such as coumarins, triterpenes, flavonoids, and benzoxazinoids are known to repress the movement and growth of certain species in the rhizobiome (Jalmi and Sinha, 2022). Plant signal molecules also cause some root-associated bacteria to synthesize auxin-like substances and soil fungi to produce volatile organic compounds that alter root length, branching and other morphological features (Schenkel et al., 2018). Plants with a rhizosheath must transfer chemical signals through the mucilage layer, as illustrated in Fig. 2c, to make contact with their rhizobiome. Soluble compounds released as signal molecules are more likely to be received in a moist environment, probably because the water streaming over the root surface brings dissolved compounds into contact with microorganisms living in water films. Roots coated with mucilage may transfer more signal molecules to a responsive rhizobiome than roots without mucilage or in dry environments, but the idea still needs to be tested.

Mucilage is a carbon source for the rhizobiome

Mucilage is composed primarily of polysaccharides, some of which are a labile carbon source for the rhizobiome. Many soil bacteria and fungi produce glycan-degrading enzymes such as galactanases, arabinofuranosidases and glucuronidases that cleave bonds in the polysaccharides, releasing glucose, fructose and other simple sugars that are absorbed and metabolized in microbial cells. Gram-negative bacteria are the most active decomposers of mucilage polysaccharides. Based on ^{13}C isotopic tracers and phospholipid fatty acid analysis, Ahmed et al. (2018a) deduced that 40% of the carbon in cell membranes of gram-negative bacteria was derived from corn nodal root mucilage after 15 d incubation. Therefore, mucilage is considered a source of carbon and energy that fuels the metabolic processes, including growth and reproduction, of the rhizobiome.

The rhizobiome produces extracellular enzymes to degrade mucilage, but these enzymes are also capable of hydrolyzing other organic compounds, such as those found in soil organic matter. It is common to observe accelerated soil organic matter mineralization after microorganisms are activated by labile carbon sources, which is known as the “priming effect” (Kuzyakov, 2002). As it contains labile carbon for microorganisms, mucilage can induce a priming effect, depending on the soil water content. In moist soil at ~80% water holding capacity, 98% of the mucilage from corn nodal roots was decomposed after 15 d incubation and this was accompanied by a significant carbon dioxide flux, indicating a positive priming effect (Ahmed et al. (2018b)). However, little mucilage was decomposed and no carbon dioxide flux was observed when soil water content was at ~30% water holding capacity in the same experiment, meaning no priming effect in drier soil (Ahmed et al. (2018b)). This may be due in part to the fact that mucilage becomes water repellent in dry soils, which could prevent polysaccharide degradation by hydrolytic enzymes (i.e., that require water to catalyze the biochemical reaction). Furthermore, if the soil organic matter was coated with water-repellent mucilage, it may be physically protected from decomposition. Therefore, we must know the mucilage chemistry and environmental conditions to predict whether root mucilage will stimulate priming by the rhizobiome.

Mucilage is a barrier that prevents pathogens from contacting the root

Root mucilage forms a physical barrier around root tips of plants in the Fabaceae and Brassicaceae families, and this barrier immobilizes fungal hyphae and spores (Fig. 3). A mucilage barrier is constructed from several compounds (e.g., arabinogalactan proteins, pectin and hemicellulose) that form a rigid biofilm-like structure. Fungal hyphae cannot penetrate the thick gelatinous mucilage covering the root tips, which prevents contact between the pathogen and the root, stopping the pathogen from infecting the root tissues. Mobile spores are also halted by the mucilage barrier. For example, a mucilage-free soybean root tip was colonized rapidly by zoospores from the Oomycete *Phytophthora*, which began to germinate within 15 min. However, there was no contact between a mucilage-coated soybean root tip and *Phytophthora* zoospores or hyphae after 30 min (Ropitiaux et al., 2020). The protective effect of soybean root mucilage was attributed to abundant xyloglucan and heteromannan molecules that cross-linked with cellulose fibers. In pea root mucilage, arabinogalactan proteins attracted 57% of the zoospores of the pathogenic Oomycete *Aphanomyces euteiches* after 4 h, thereby preventing infection of the pea root (Cannesan et al., 2012). The key role of arabinogalactan proteins was confirmed by adding β -glucosyl Yariv reagent, which deactivated the arabinogalactan proteins and lowered the attraction efficiency for zoospores from 57% to 32% (Cannesan et al., 2012). Pathogen infection by *A. euteiches* is the result of chemotactic attraction of zoospores to the root, encystment within root tissues followed by cyst germination. This suggests that mucilage acts like a viscous shield that can physically protect roots from such infections.

Extracellular DNA inactivates infectious root pathogens

Mucilage inactivates infectious root pathogens because it contains chemical substances that inhibit spore germination and limit mycelial growth. These chemical substances include extracellular DNA and histones, which bind to pathogenic bacteria and kill them. Extracellular DNA can inactivate root pathogens in two ways. First, extracellular DNA can ‘trap’ pathogens, as described in the section “Biotic stress and root mucilage”. Second, extracellular DNA is directly toxic to pathogens because it disrupts cell membranes and causes cell lysis by chelating cations that stabilize the microbial cell structure (Mulcahy et al., 2008). Pea root tips that secreted extracellular DNA had only 5% root infection due to the fungal pathogen *Nectria haematococca*, but the infection rate reached 100% after adding exogenous DNase I, which degrades the extracellular DNA (Wen et al., 2007). Histone also appears to be directly toxic to pathogens. Live pathogenic bacteria populations were reduced by 55% following exposure to $10\ \mu\text{g mL}^{-1}$ of histone H4 extracted from pea root, and the effect vanished when the anti-histone H4 antibody was added to the exposure media (Tran et al., 2016). The protective effect of extracellular DNA and histones may be enhanced by the presence of other antimicrobial substances that are exuded by roots (e.g., flavonoids, strigolactones), but this still needs to be established. These examples are compelling evidence that mucilage helps plants to inactivate dangerous root pathogens.

Research methods for mucilage collection

Mucilage is released from roots, and most roots grow below the soil surface. It is difficult to measure mucilage from these roots without destructively sampling the plant. However, it is possible to get mucilage from undisturbed, living plants that have aerial roots, such as the brace roots of corn. Aerial roots grow above-ground, so they can be cut at the soil surface and immersed in a plastic cylinder filled with water for 24 h to stimulate mucilage production. When the cylinder is removed, the brace root is covered with mucilage, which is then collected with a syringe to quantify the daily mucilage production and analyze its chemical composition. This is a suitable method to evaluate mucilage production in aerial roots of plants growing in field or controlled environments, since

Fig. 3 Schematic representation of plant root defenses associated with mucilage secretion. Mucilage creates a sticky physical barrier that adhere to microbial spores, preventing the spore from coming into contact with root cells. Mucilage also contains lytic substances like extracellular DNA, histones and other antimicrobial substances that are directly or indirectly toxic to pathogenic microorganisms.

it allows for repeated sampling of the same plant to understand its response to abiotic and biotic stresses, and to monitor the mucilage production at key growth stages.

In contrast, roots growing in the soil profile must be sampled destructively by excavating the root mass, then manually removing most of the adhering soil, followed by brushing and washing to clean the roots. Intense root manipulation is likely to create artifacts that affect mucilage production and its chemical composition. Consequently, hydroponic and aeroponic methods are generally considered to be more reliable ways to collect mucilage from plants with fibrous and taproot systems.

Mucilage is commonly sampled from plant roots in axenic hydroponic systems, which are free of other organisms. After the seedling is established and its roots are partially or completely immersed in the nutrient solution, which is replenished regularly with drip irrigation, the hydroponic system is flushed to remove salts and other residuals. During the measurement period, mucilage secreted into fresh nutrient solution is recovered by freeze-drying, followed by centrifugation, filtration and dialysis steps to isolate

mucilage fractions. The method provides a snapshot of the mucilage production and its characteristics at a defined point in time. However, it is not the best way to collect mucilage for follow-up studies because mucilage loses its structural properties after it is exposed to the nutrient solution, and these cannot be restored after freeze-drying. Mucilage collected in hydroponic systems is similar to, but not identical to the mucilage released under field conditions. Clearly, plants grown in hydroponic environments are not exposed to the same physical, chemical and biological stresses (e.g., inadequate water supply, nutrient deficiency, pathogens) that are experienced routinely by field-grown plants. Therefore, mucilage production and mucilage chemistry in hydroponic systems can only approximate how plant roots act in natural field environments.

Aeroponic systems, which expose plant roots to nutrient-containing aerosol droplets, are an interesting alternative for sampling root mucilage. A 'mucilage separator' for aeroponic systems allowed researchers to collect hydrated, intact mucilage gel (Zickenrott et al., 2016). Briefly, this involves seed germination under aeroponic condition, followed by seedling placement inside a polyethylene bottle that was installed on a custom-designed, rotating tray. As the tray rotated, the centrifugal force separated individual droplets of mucilage from the tip of the developing radicle, and the mucilage droplets were collected within 15 min of secretion from the root. This is a reliable method to recover mucilage from young, recently-germinated seedlings in the first 10 d of their growth. However, more work is needed to adapt the method to older plants (>10 d), which need more space to accommodate their root growth. The aeroponic method for mucilage collection has advantages because it avoids excessive root manipulation associated with excavating plant roots from soil, and it prevents root exposure to salts in hydroponic nutrient solutions. Further development of the aeroponic method will provide us with deeper insight into the multiple functions of root mucilage in diverse plant species.

Summary and outlook

Mucilage is responsible for rhizosheath formation and protects root meristems as they extend vertically and laterally in the soil profile. However, it is emerging that mucilage has several other vital functions, including water retention, rhizobiome assembly and plant defense responses in the rhizosphere. The water-attracting functions of mucilage are critically important in regions where soil water supply is less than crop water requirements, either due to natural aridity or because of an emerging water shortage associated with global climate change. Since mucilage sustains the water reserves in the rhizosphere, it is interesting to consider how plant species adjust their mucilage production in water-deficient soils. This could lead to the identification of drought-tolerant root phenotypes for agricultural use. Cultivars with superior mucilage properties could be included in crop rotations or retained in crop breeding programs. Since mucilage mediates the release of plant signals to potential symbiotic and beneficial soil microorganisms, it needs to be considered in understanding crop associations with plant growth-promoting rhizobacteria that occur naturally in field soils or that are added as inoculants. Finally, the defensive attributes of mucilage need further investigation, as certain mucilage traits could boost the inherent resistance of plants to infective pathogens. Enhancing the ability of plants to protect themselves from diseases is expected to reduce our reliance on synthetic pesticides. Therefore, ongoing research into root mucilage and its functions will improve our understanding of plant resilience in an increasingly stressful world.

Abstract

Plant root exudates are atoms and compounds that are released from living root cells. Root exudate chemistry and concentrations depend on the plant species and environmental conditions. These exudates increase microbial growth and activity in the rhizosphere, compared to the bulk soil. Some root exudates are signal molecules that attract beneficial and mutualistic microorganisms to grow in and around the roots. Other root exudates provide chemical inhibition and biological control of disease-causing organisms. Methodological advances that improve our fundamental understanding of root exudation will be important to improve plant health and agricultural sustainability in the future.

Key points

- Root exudates are the medium by which plants communicate with the soil microbiome.
- Plant physiology determines the inherent composition of root exudates, which is then modulated by abiotic and biotic factors.
- Root exudates allow plants to sense their soil environment and adapt their root architecture accordingly.
- Root exudates can enhance nutrient availability by solubilizing immobile phosphorus while restricting export of mobile nitrogen.
- Root exudation exerts the selecting force that determines the rhizosphere microbiome.
- Root exudates released by constitutive and induced processes protect plants against root pathogens.

Introduction

The rhizosphere is at the interface of the plant root system and the soil environment. Here, plant roots sense the abiotic and biotic factors in the surrounding soil and respond directly to them by modifying root growth and interacting with the matrix of the root-associated soil. The ability of a plant to adjust root growth directly impacts the development and survival of plants and indirectly affects soil ecological functions. This chapter explains how plant roots interact with the abiotic and biotic components of soil, transforming soil that was originally part of the bulk environment into the dynamic rhizosphere, all through the secretion of root exudates.

Root exudates are chemical forms released from plant roots into the surrounding soil. Possessing diverse chemistry, root exudates include inorganic atoms and compounds, as well as organic compounds of both low- and high-molecular weight. The amount and chemical composition of root exudates released vary in space and time, creating a dynamic interface between roots and their associated soil. At the scale of an individual plant, root exudation depends on plant genetics, stage of development, root system architecture and nutritional status. Furthermore, the type of exudates and rate of release are influenced by environmental factors related to abiotic (e.g., light, atmosphere, temperature, soil texture, moisture, salinity) and biotic conditions (e.g., plant competition, herbivory, microbial relationships). Many of these environmental factors fluctuate with time, which means that root exudation adapts to maintain the rhizosphere functions.

Root exudates often change the soil microenvironment around the roots for the benefit of plants. For example, root cells secrete organic acids that lower the soil pH and dissolve phosphate minerals, which liberates phosphate ions that can be absorbed by the root. Some root exudates act as signal molecules, like the strigolactones. These terpenoid-derived molecules allow symbiotic fungi to detect a potential plant host. In addition, strigolactones function as plant hormones that regulate several developmental processes, allowing shoot and root architecture to adapt to environmental conditions. Many root exudates are simple organic substrates that are readily metabolized by free-living and root-associated microorganisms (e.g., archaea, bacteria, fungi). The free-living microorganisms derive energy and nutrients from these substrates to support their activities. Free-living microorganisms living near the root are known to transfer nutrients to plants, provide hormonal control of plant growth and support plant immunity. Hence, the connection between root exudates and microbial responses in the rhizosphere is a key determinant of plant tolerance to fluctuating growing conditions.

From this perspective, root exudation appears to be an adaptive strategy that ensures plant survival and allows for effective communication between plant roots and soil microorganisms. While immense progress has been made in the analysis of root exudates and their impact on processes in the plant-soil system, more insights are forthcoming. In this chapter, we discuss the emerging techniques that can deepen our understanding of root exudates and the outcomes of plant-microbial communication for rhizosphere functions. Such knowledge may allow us to use root exudates as an indicator of plant health, with regards to plant nutrition and disease suppression, as well as provide insight into the role of the rhizosphere as both a source and sink of greenhouse gases via the release of root exudates. Root exudation could reflect the degree to which inherent biological processes are optimized. There are indications that plants with a particular profile of root exudates might be sufficiently well-nourished that they require less fertilizer or have adequate immunity and growth potential to reduce pesticide use. Likewise, the control that root exudates exert on microbial metabolism suggests the potential for engineering the rhizosphere to manage greenhouse gas emissions from soil. Hence, there is considerable interest in studying root exudation as a means to achieve economical crop yield targets while lowering agrochemical inputs and greenhouse gas emissions. These possibilities are fully aligned with the principles for sustainable intensification of agriculture.

Composition of root exudates

There is a vast diversity of root exudates. We define root exudates as atoms and compounds released passively and actively from plant roots as solids, liquids and gases into the soil environment. Consequently, root exudates range from atoms to complex macromolecules. They can be inorganic atoms and compounds, like protons, bicarbonate, and carbon dioxide (Table 1), as well as low- and high-molecular weight organic compounds like amino acids, simple sugars, organic acids, fatty acids, sterols, plant growth factors, vitamins, enzymes and proteins, phenolics, terpenes and terpenoids (Table 2).

Plants release inorganic and organic substances in their root exudates. As is evident from the divergent chemical structures of inorganic and organic exudates, different mechanisms are responsible for their synthesis, transport and release. As such, there are unique metabolic processes, organelles, cells and tissues involved in the production pathways of various exudates.

Table 1 Examples of inorganic atoms and compounds exuded by plants and exporter protein families related to their release.^{a–c}

Chemical Class	Exporter Families ^d	Examples
Ionic Atoms and Compounds	ATPase, Anion Channels ^e	Bicarbonate (HCO ₃ ⁻), hydroxide (OH ⁻), hydrogen proton (H ⁺)
Gas Compounds		Carbon dioxide (CO ₂), hydrogen gas (H ₂)

Root exudate production

Origin and secretion of inorganic atoms and compounds as root exudates

The secretion of inorganic root exudates is crucial to basal processes, like gas diffusion and ion absorption by roots. For example, catabolic activities in roots continually release carbon dioxide (CO₂). In addition, the steady absorption of cations (e.g., ammonium) by plant roots requires the exudation of inorganic hydrogen protons to maintain the electrostatic charge balance of cellular membranes. Thus, the exudation of these inorganic atoms and compounds are vital to root physiology.

Fig. 1 Root exudate synthesis, transport and release processes. Most root exudates are organic compounds that originated as photosynthates, the carbon-based compounds produced from the conversion of photons into chemical energy via photosynthesis (A). Photosynthates are conveyed from chloroplasts in leaves to the root system through the phloem vascular tissue. In roots, photosynthates can be released directly from the epidermal cells as is or modified by other metabolic processes prior to release as root exudates. Root exudates must cross at least one plasma membrane passively or actively, and often via an enzyme transporter. Primary metabolites (B) include organic acids, amino acids and sugars. Some organic acids have a well-characterized export mechanism, like malic acid by ALuminum-activated Malate Transporters (ALMT), but the export pathways are unknown for most organic acids, amino acids and sugars. The known export pathways for secondary metabolites (C) include transporters of the ATP-Binding Cassette (ABC) family that are responsible for strigolactone release from roots. ABC transporters may be responsible for the export of flavonoids, along with Multidrug and Toxic compound Extrusion (MATE) transporters. Root exudates that are inorganic atoms (e.g., hydrogen protons), or compounds, like bicarbonate ions and carbon dioxide (D), do not originate directly from photosynthates but could be transferred from above-ground tissues to roots by the phloem. Hydrogen protons are exported from roots by H^+ -ATPases transporters, while anion channels are purported to facilitate the diffusion of bicarbonate ions into the soil environment. Carbon dioxide does not require an enzyme transporter for its exudation because it is released passively from roots via simple diffusion. Export pathways requiring experimental validation are indicated with an asterisk. Adapted from Sasse J, Martinoia E and Northen T (2018) Feed your friends: Do plant exudates shape the root microbiome? *Trends in Plant Science* 23: 25–41. <https://doi.org/10.1016/j.tplants.2017.09.003>.

Although some gases and inorganic solutes could originate from above-ground plant organs, the vast majority of inorganic root exudates are derived from the basal physiological processes occurring in roots. These processes are distributed throughout the root cells. In the mitochondria, the tricarboxylic acid cycle generates CO_2 that is released via root respiration, while the autoionization of water in the cytosol produces hydrogen protons and hydroxides. These processes occur continually, ensuring a steady emission of gases and ongoing production of inorganic root exudates.

Root exudates must cross the plasma membrane of the root cells before they enter the surrounding soil (Fig. 1). Some inorganic root exudates do so by passive transport. This mode allows the free movement of inorganic compounds across the membrane along steep electrochemical gradients and includes both simple and facilitated diffusion. Simple diffusion permits small, uncharged exudates, like gases (e.g., CO_2), to freely move through the lipid bilayer (Canarini et al., 2019). In contrast, charged inorganic exudates must pass the lipid bilayer by facilitated diffusion. This transport mode is likely the case for hydroxide and bicarbonate ions, which must move through channel or uniporter transmembrane proteins across the plasma membrane. These forms of passive diffusion permit the free flow of inorganic root exudates into the rhizosphere.

While passive transport accounts for the release of most inorganic root exudates, a direct expenditure of energy is required for hydrogen protons to cross the plasma membrane. Energy-driven movement of hydrogen protons and other substances is known as active transport. Direct export of hydrogen protons requires primary active transport, where uniporter transmembrane proteins, known as proton pumps (H^+ -ATPases), are coupled with adenosine triphosphate (ATP) hydrolysis to transfer hydrogen protons across the lipid bilayer. However, hydrogen protons can also pass through the plasma membrane indirectly if coupled to the secondary active transport of another compound via symporter and antiporter transmembrane proteins (discussed in section “Secretion of organic root exudates”). Active transport pathways guarantee hydrogen proton export into the rhizosphere, which is essential for electrochemical charge balance and controls the pH around the root.

Origin and transport of organic compounds to root epidermal cells

Most root exudates are organic compounds. The reason is that plants allocate a considerable amount of their total fixed carbon (5–21%) to root secretion, even during periods of stress (Haichar et al., 2014). Many of these organic compounds are enriched in nitrogen. In fact, the nitrogen content in root exudates can be up to 15% of the total nitrogen acquired by the plant during the growing season (Sasse et al., 2018). This substantial dedication of carbon and nitrogen to manufacture compounds that are then released from the plant reflects the necessity of root exudation for the plant's well-being.

Of the organic compounds, those categorized as primary metabolites (e.g., amino acids, organic acids, sugars) are exuded in greater quantities than secondary metabolites (Canarini et al., 2019). Primary metabolites are the dominant exudates because they participate in a number of fundamental physiological processes, such as nutrient acquisition. In contrast, secondary metabolites (e.g., flavonoids, aromatics) are a large group of more than 100,000 specialized organic compounds that are released under specific circumstances, unrelated to the basal physiology of plants (Haichar et al., 2014).

Whether primary or secondary metabolites, all organic root exudates and their precursors depend upon the carbon and energy obtained from photosynthesis (Fig. 1). The chlorophyll-containing shoot tissues are where photosynthesis converts photons into chemical energy via the *de novo* synthesis of glyceraldehyde-3-phosphate, the foundational molecule of photosynthates (i.e., sugars and other organic compounds). Normally, complete *de novo* synthesis is energetically expensive, but photosynthesis harnesses the free energy of photons. Consequently, photosynthesis permits the energetically efficient production of organic root exudates.

Other metabolic pathways (e.g., tricarboxylic acid cycle, phenylpropanoid pathway, glutamine synthetase-glutamate synthase cycle) can further modify the glyceraldehyde-3-phosphate into a variety of compounds that are eventually secreted by roots. For primary metabolites, such as sugars and amino acids, only a few biochemical steps are required to transform glyceraldehyde-3-phosphate into these compounds. In contrast, engineering macromolecules for exudation is a complex process. For example, the construction of extracellular enzymes and other proteins involves amino acid synthesis, transcription, translation and folding into their functional structures. Thus, the rate of organic root exudate synthesis is related to the number of metabolic pathways required for their creation.

The metabolic pathways involved in the synthesis of organic root exudates can occur either in a specific organelle or at multiple sites within plant cells. For example, photosynthesis occurs in chloroplasts whereas the tricarboxylic acid cycle occurs in mitochondria. As the tricarboxylic acid cycle supports basal metabolism in all cells, it occurs in shoots and roots and supports a number of functions, in addition to the production of root exudates. In contrast, the phenylpropanoid pathway involves metabolons in the cytosol and endoplasmic reticulum (Biała and Jasiński, 2018). Phenylpropanoids produced within a particular cell can then be transferred to other cells for further biosynthesis into secondary metabolites, like flavonoids and coumarins. For example, phenylpropanoid production may originate in leaves using photosynthates obtained from chloroplasts, which are then transported to the root system so isoflavonoid synthesis can occur in the root cortex. This network means that a significant amount of cellular machinery throughout the plant is required for the production of the diverse root exudates detected in the rhizosphere.

In summary, organic root exudates are formed from photosynthates, byproducts of the tricarboxylic acid cycle, phenylpropanoids and many other organic compounds that originate in shoot cells and are gradually conveyed to the roots. These organic substances may be exuded through the root epidermis without further modification or altered within root cells before their secretion. The degree to which a particular organic root exudate is synthesized in the shoot versus modified in the root is not known, nor do we fully comprehend the time between the inception of a given exudate—or its precursor—in the shoot and subsequent transfer to the root. Transport of organic substances from the shoots will be controlled by the rate at which these materials are loaded into the vascular tissue of the phloem. Phloem loading occurs continuously, but plants can up- and down-regulate phloem transport rates in response to environmental triggers (Gargallo-Garriga et al., 2018). For example, water stress can result in increased loading of certain photosynthates (e.g., proline, pinitol) into the phloem (Canarini et al., 2016). Hence, phloem loading can be both a constitutive and induced response for the transfer of photosynthates and other organic compounds to roots, which eventually results in their exudation into the soil.

Transport of photosynthates from leaves to roots via the phloem requires that photosynthates first travel symplastically from the mesophyll cells to bundle sheath cells and finally reach the phloem parenchyma cells (Thompson and Wang, 2017). To enter the phloem itself, these organic compounds may continue to travel symplastically via plasmodesmata, which serve as a conduit between the phloem parenchyma and sieve element-companion cell complex of the phloem. If plasmodesmata are absent, organic compounds will be released into the apoplast but require active transport to enter the sieve element-companion cell complex. The availability of symplastic or apoplastic pathways for metabolites into the phloem depends on the plant species. Transfer of organic compounds through the phloem is controlled by concentration gradients that create pressurized bulk flow from the source to the sink. Phloem loading with organic metabolites causes water diffusion from the xylem into the phloem. The resulting change in turgor creates sufficient pressure for mass transport through the phloem to the sink, in this case, roots. Rapid phloem unloading will empty the sieve tube elements and permit water diffusion back into the xylem, creating a positive feedback loop that assures continued movement of the photosynthates into roots. Photosynthates are unloaded from the sieve element-companion cell complex of the phloem through funnel plasmodesmata to the phloem-pole pericycle. Phloem unloading for simple metabolites occurs in a convective manner with mass flow and diffusion, whereas larger macromolecules are unloaded in batches to the phloem-pole pericycle. If the compounds are <27 kDa, the organic metabolites may diffuse throughout the root cortex and reach the root epidermis cells (Ross-Elliott et al., 2017). Our current understanding is that larger metabolites remain in the phloem-pole pericycle, where they are likely degraded. Thus, while root exudates include large macromolecules like proteins, these compounds do not appear to originate from shoot biomass and must be constructed in the root cells.

Fig. 2 Release of root exudates. Root exudates can travel from the phloem by the apoplastic (extracellular) or symplastic (intercellular via plasmodesmata) pathways. In the root differentiation zone (A), root exudates move through the pericycle by apoplastic or symplastic processes but must reenter the symplast at the endodermis to traverse the Casparian strip. Upon crossing the Casparian strip, root exudates travel by apoplastic or symplastic routes until they reach the root epidermal cells, where they pass the cell membrane via the apoplast to enter the soil environment. In the undifferentiated meristematic zone (B), root exudates can use apoplastic or symplastic pathways to move through all root tissues (i.e., pericycle, endodermis, cortex) due to the absence of the Casparian strip. However, exudates in the symplast must move into the apoplast to exit the plasma membrane of root epidermal cells and reach the surrounding soil. Adapted from Canarini A, Kaiser C, Merchant A, Richter A and Waneke W (2019) Root exudation of primary metabolites: Mechanisms and their role in plant responses to environmental stimuli. *Frontiers in Plant Science* 10: 157. <https://doi.org/10.3389/fpls.2019.00157>.

Movement of simple organic compounds from the phloem-pole pericycle to the root epidermis depends on whether their exudation occurs in undifferentiated or differentiated root tissue (Fig. 2). In undifferentiated root tissue, organic compounds can travel by either apoplastic or symplastic pathways through the endodermis, cortex and epidermis (Canarini et al., 2019). In differentiated tissue, the simple organic compounds must travel symplastically—at least once—to cross the Casparian strip of the developed endodermis. Additionally, differentiated tissue has fewer plasmodesmata than undifferentiated tissue, which limits the quantities and movement of organic compounds. These constraints mean that far less exudation of simple organic compounds occurs from differentiated root tissues, such as lignified structural roots, than from undifferentiated tissue, like those of the root tip meristematic zone, where the majority of root exudation is expected to take place.

Secretion of organic root exudates

All organic root exudates must exit the plasma membrane of root cells before entering the rhizosphere (Fig. 1). Like the inorganic root exudates, organic root exudates can cross the lipid bilayer of root cells by passive or active means, depending on the size and charge of the compound. Although small, nonpolar organic compounds (e.g., urea, glycerol) can traverse the plasma membrane by simple diffusion, most organic root exudates are passively transported via facilitated diffusion (Sasse et al., 2018; Canarini et al., 2019). Transmembrane proteins like Aluminum-activated Malate Transporters (ALMT) are known to facilitate the exudation of malic acid. Other substrate-specific transporters are likely responsible for facilitating the diffusion of other organic acids as well as amino acids and sugars. Thus, both simple and facilitated diffusion are responsible for the passive release of organic exudates from root cells into the rhizosphere.

Simple and facilitated diffusion allows for the spontaneous exudation of organic compounds from roots, but plants do exert some control over the passive transport of such root exudates. These mechanisms include downregulating gene expression for the transmembrane proteins performing facilitated diffusion, the active reassimilation of root exudates or actively storing root exudates in the plant cell vacuole (Canarini et al., 2019). For example, wheat (*Triticum aestivum* L.) roots can take up some organic exudates at rates 1–175% greater than their efflux via secondary active transport (Warren, 2015). Uncertainty exists regarding whether the benefits from conserving carbon resources outweigh the energy costs required for these controls over the passive release of organic root exudates. Yet, both passive root exudation and the carbon-conserving mechanisms that control this process are physiological traits conserved by plants throughout their life history. As such, the persistence of these plant behaviors despite evolutionary pressures suggests their essential roles in the survival of plants.

Active transport of some organic root exudates occurs by primary active transport, similar to protons. Like H^+ -ATPases, the primary active transport of organic root exudates occurs through uniporters directly coupled with ATP hydrolysis that move organic substances across the plasma membrane against their electrochemical gradient. Nucleotides, peptides, fatty acids, siderophores and strigolactones are exuded in this manner via ATP-Binding Cassette (ABC) transporters, a family of uniporters that is ubiquitous in plants (Vives-Peris et al., 2020). ABC transporters are also thought to export a number of other secondary metabolites from roots into the soil environment, but as yet this function has not been confirmed.

Alternatively, organic root exudates can move across the root epidermis by secondary active transport and vesicle transport mechanisms. Secondary active transport of organic root exudates requires ATP hydrolysis, but the energy is transferred to a H^+ -ATPase rather than the transmembrane protein (Canarini et al., 2019). This pump generates an electrochemical gradient of protons across the plasma membrane, creating energetically favorable conditions that allow the export of organic root exudates. Once this gradient is established, the organic root exudates and protons may be transferred by the transmembrane protein in parallel (via symporters) or in opposite directions (by antiporters). Symporter systems for organic compounds, like inositols, are found in the plasma membranes of vacuoles but are not yet associated with the release of organic compounds into the rhizosphere (Sasse et al., 2018). However, antiporters are known to be responsible for the export of citrate and some phenolics and alkaloids from roots into the rhizosphere, such as through the Multidrug And Toxic compound Extrusion [MATE] transporters (Sasse et al., 2018). Vesicle transport (exocytosis) differs from primary and secondary active transport because it does not involve a transmembrane protein. Instead, this process relies on the formation of vesicles containing root exudates near the endoplasmic reticulum or the Golgi apparatus (Weston et al., 2012). After the vesicle membrane fuses with the plasma membrane and unfolds, the organic root exudates cross the lipid bilayer and are extruded through the cell wall into the soil environment. Vesicle transport is responsible for the exudation of high-molecular weight compounds, such as secondary metabolites.

Overall, most organic root exudates seem to be exported to the soil environment via passive transport rather than active transport. This observation is supported by the fact that individual plant metabolites are more concentrated in the cytosol of root cells ($0.1\text{--}10\text{ mmol L}^{-1}$) than in the rhizosphere ($<0.001\text{ mmol L}^{-1}$; Oburger and Jones, 2018). The 100- to 1000-fold concentration difference of organic substances within the root versus outside the root creates a steep electrochemical gradient that allows for simple or facilitated diffusion. Passive transport requires no direct energy expenditure, and thus should be a preferred pathway for most organic exudates. However, larger organic compounds must be transported via active processes. Research is needed to identify the transporter proteins, energetic requirements and physiological factors that control the active transport of the high-molecular weight organic compounds found in root exudates.

Factors affecting root exudation

The release of root exudates into the rhizosphere is determined by plant physiology and growing conditions. Characteristics of the plant (i.e., genetics, life stage, root morphology, nutrition) determine the intrinsic quantity and chemical composition of root exudates (Fig. 3). Still, plants exhibit considerable phenotypic plasticity that allows them to respond to the external environment by tailoring their profile, concentration and release rate of root exudates. The environmental triggers can be both abiotic and biotic in nature. Some abiotic factors, for example water stress (drought and flooding), can increase the total carbon exuded by plants, whereas exposure to biotic factors, such as herbivory and pathogens, lead to an upregulation of secondary metabolite exudation by the plant. Abiotic and biotic factors can have a profound effect on the chemistry, concentration and rate that root exudates are released into the rhizosphere.

Plant physiology

Root exudation is affected by the life history of plant species. Fast-growing, exploitive plant species (*r*-strategists) tend to have greater rates of carbon release through root exudation than slow-growing, conservative plant species (*K*-strategists; Guyonnet et al., 2018). There are also distinct patterns of root exudation at the phylogenetic level. For example, some root exudates are unique to specific taxonomic groups, like benzoxazinoids, which are secondary metabolites released only by cereal species of the *Poaceae* (Massalha et al., 2017; de Bruijn et al., 2018). However, root exudate profiles can differ among cultivars of the same species, as demonstrated for thale cress (*Arabidopsis thaliana*). Root exudate analysis of 19 cultivars of *A. thaliana* showed more variation in the glucosinolates, followed by flavonoids and then phenylpropanoids (Sasse et al., 2018). This finding suggests that root exudation might explain plant fitness, meaning the ability of plants to survive and reproduce in environments that are sometimes stressful with difficult growing conditions.

The developmental stage of the plant also affects quantity and composition of root exudation. In *A. thaliana*, there are more sugars released into the rhizosphere during the early growth stages, but more amino acids and flavonoids are exuded in the later growth stages (Vives-Peris et al., 2020). The amount of exudate produced by roots peaks during the vegetative growth and onset of reproduction and is least at seedling emergence and senescence stages (Haichar et al., 2014). In general, this temporal variation in the exudation rate is associated in part with the effects of a particular growth stage on photosynthesis, since the generated photosynthates are the main source of energy and carbon required to produce, transport and release root exudates into the rhizosphere.

Fig. 3 Factors that affect root exudation (A–C) and its functions (D–G). Plant physiology (A) as well as abiotic conditions (B) and biotic stressors (C) will cause plants to modify the composition and rate of root exudation. In turn, root exudates serve a variety of functions for plant growth and development. Release of strigolactones can modify root architecture by elongating root hairs and increasing their density (D). Some root exudates can mobilize nutrients, like organic acids that solubilize phosphorus by chelating iron (E). Root exudates are signals that alert soil microorganisms to move towards the root surface. For example, flavonoids attract rhizobia to bind onto root hairs, which initiates their mutualistic symbiosis (F). Plants can also protect themselves with root exudates, such as with protons that acidify the rhizosphere, creating an inhospitable environment for some pathogens (G).

Spatial variation in root exudation is clearly related to the root system architecture. The exudation of primary metabolites occurs largely at the root tip, most likely from the meristematic zone where both the lack of a Casparian strip and abundance of plasmodesmata would permit the efficient export of these exudates from the phloem (Canarini et al., 2019). Sloughed border cells from the root are an important source of root exudates, releasing secondary metabolites, like flavonoids and proteins, into the rhizosphere (Massalha et al., 2017; Sasse et al., 2018). Variation in this pattern occurs in some plants with specialized root structures and unique exudation patterns. For example, white lupin (*Lupinus albus*) grows cluster roots that exude large quantities of organic acids, as well as protons, phenolics and enzymes (Sasse et al., 2018). To encourage nodulation, legume species (*Fabaceae* spp.) release specific flavonoids from the root hairs and cortical cells of branching roots, rather than from sloughed root border cells (Haichar et al., 2014). Thus, root morphology will affect the spatial pattern of root exudation.

Plants change the chemistry and rates of root exudation according to their nutritional status. Nitrogen availability is well-known to influence root exudation. During periods of nitrogen stress, plants tend to reduce the quantities of amino acids transported to the roots (Canarini et al., 2019). For example, maize (*Zea mays*) growing under nitrogen deficient conditions reduced the amino acid concentration of root exudates by 75%, on average, compared to the control (Carvalho et al., 2011). Increasing the nitrogen availability also affects root exudates, but the magnitude and direction of the response vary among plant species and growing conditions. Studies with perennial ryegrass (*Lolium perenne*) demonstrated a 153% decrease in below-ground carbon allocation with higher levels of ammonium nitrate fertilizer application (Pausch and Kuzyakov, 2018), whereas an experiment with maize found that increasing the urea-nitrogen application by 130 kg N ha⁻¹ boosted total root exudation by 80% (Zhu et al., 2016). This disparity in effects may result from the greater absolute rate of nitrogen (560 kg N ha⁻¹) in the perennial ryegrass study, whereas maize received up to 160 kg N ha⁻¹. The form of mineral nitrogen fertilizer may have affected the root exudation response as well. Other reports indicate that ammonium fertilizers stimulate more sugar exudation than nitrate fertilizers (Canarini et al., 2019). Similar effects were shown for phosphorus-stressed plants. In soil environments with low phosphorus availability, some plants change their root exudate profile, increasing the production of strigolactones (See section “Plant root architecture and sensing”), organic acids and phosphatase enzymes (See section “Nutrient mobilization”). It is likely that the fertilizer application rate and fertilizer source will induce changes in the composition of root exudates, but this remains to be confirmed for other nutrients and plant species.

Abiotic controls

Root exudation is also affected by abiotic factors, like light, atmosphere, temperature, soil texture, moisture and salinity. Similar to the effects of plant growth and development on the release of organic root exudates, light, atmospheric composition and

temperature strongly influence the photosynthesis rate of plants, and thus the intensity of root exudation. Extended photoperiods stimulate root exudation, likely due to greater photosynthesis. Higher CO₂ levels provide the plant with more carbon for photosynthesis and substantially increase the amount of carbon exuded by roots. For example, a study using ¹⁴C-isotope tracing found that an elevated CO₂ level of 720 ppm increased carbon in the rhizosphere by 18% for perennial ryegrass and by 47% for wheat, on average (Pausch and Kuzyakov, 2018). Temperature can also increase the exudation of organic acids and other compounds (Vives-Peris et al., 2020). The relevance of some of these effects on root exudation (i.e., atmosphere and temperature) is expected to grow in the future, as anthropogenic activities continue to elevate CO₂ concentrations in the atmosphere, subsequently raising the global temperature via the greenhouse effect. Consequently, the release of root exudates may increase with climate change, but this assumption requires robust analysis to account for all factors at play (e.g., flooding) when considering the future climate's impact.

Soil characteristics, like texture, moisture and salinity, can also alter root exudation rate and composition. Soil texture is thought to impact root exudates since clay particles are more reactive and have greater surface area than silt or sand particles (Nguyen, 2009), which could impede the diffusion of root exudates in soils with higher clay content. Two factors that create osmotic stress for roots, moisture and salinity, will likely have a profound impact on root exudation. Water stress increases the amount of carbon-based compounds released by roots. For example, drought conditions increased the proportion of carbon exuded by crested wheatgrass (*Agropyron cristatum*) by 71%, while flooding conditions increased the proportion of exuded carbon by 45% (Vives-Peris et al., 2020). Roots experiencing osmotic stress also modulate the chemistry and concentration of their root exudates. Drought and saline conditions stimulate the exudation of organic acids, flavonoids and terpenoids, and it is postulated that these exudates were signal compounds meant to recruit microbes and initiate symbioses that could alleviate the stress in species like maize and soybean (*Glycine max*; Vives-Peris et al., 2020; Williams and de Vries, 2020). However, other studies found no change in root exudate composition under water stress or saline conditions, as found for sunflower (*Helianthus annuus*), suggesting a species-dependent effect (Canarini et al., 2016). Nevertheless, these stress-induced changes in root exudation may be an adaptive strategy that improves plant survival and warrant further investigation to determine which root exudate compounds are the key to improve plant tolerance to stress.

Biotic controls

In natural environments, plants are confronted with numerous biotic challenges. Competition with other plants, herbivory from predators, disease-causing pathogens and other antagonistic interactions will impact root exudation. To defend against competitors, some plants release allelochemicals from their roots to repel the advances of the neighboring plants into their rhizosphere via inhibiting seed germination and preventing root cell elongation (Vives-Peris et al., 2020). While plant species have adapted to allelochemicals, this mechanism still protects the exuding plant to a degree. Likewise, herbivory triggers the emission of volatile organic compounds from roots that can signal the danger to all plants in the vicinity and enlist microorganisms to protect the plant. This response is seen in maize cultivars that emit sesquiterpenes to recruit nematodes that feed on the herbivorous larvae of Western corn root worm (*Diabrotica virgifera*; Preece and Peñuelas, 2020). Concurrently, the plant will often exude readily-metabolizable organic compounds and signals molecules that stimulate the action of nutrient-cycling microorganisms to aid in compensatory plant growth (Williams and de Vries, 2020). Plants exude metabolites that attract immune response-inducing microbes, to provide natural biocontrol (Sasse et al., 2018). Such mechanisms can partially protect the plant from biotic stresses.

There are other biotic interactions that affect root exudation. Rhizosphere microorganisms can rapidly assimilate the simple organic compounds in root exudates, based on the elevated respiration in the rhizosphere compared to the bulk soil. Microbial depletion of these organic substrates will preserve the steep electrochemical gradients between the root cytoplasm and soil solution, which is necessary for passive diffusion (Haichar et al., 2014). In addition, microbes release metabolites that bind with receptors on the root surface cells and modulate root exudation (Zipfel and Oldroyd, 2017). There is also evidence that certain microbial metabolites increase the solubility of the plasma membrane in root cells, which enhances the diffusion of root exudates (Oburger and Jones, 2018). Through these mechanisms, rhizosphere microorganisms exert some control over root exudation.

Functions of root exudates

There is a growing appreciation for the multifunctional nature of root exudates. Root exudation allows plants to adjust to and tolerate fluctuations in their growing environment, maintain their nutrient status, interact with their microbial neighbors, and ensure their healthy growth and development (Fig. 3).

Plant root architecture and sensing

Once released, root exudates interact with the soil, whether by adsorbing to soil particles, dissolving in soil pore water, or diffusing into the air-filled compartment of the pore. Although the residence time of a given root exudate is short due to their rapid assimilation by soil microbes, their brief interaction with the soil matrix can signal the quality of the soil microsite (i.e., nutrient availability) to the neighboring roots, as well as the origin root itself. This will allow the plant to optimize their root architecture in variable environments and explains the plasticity in root development that is characteristic of successful, high-yielding plants.

Changes in root morphology are associated with some of the primary metabolites. For example, high concentrations of L-glutamate (10^{-5} M) trigger root tip branching in *A. thaliana*, likely to enhance nutrient foraging (Canarini et al., 2019). Organic acid anions are another indicator of the soil nutrient status that induce changes in root growth. Malate indicates low phosphorus availability by transporting iron to the root tip (Canarini et al., 2019). This signal triggers a modification in the root morphology, arresting growth at the root apical meristem and stimulating lateral root branching. This response coincides with sugar accumulation in roots, suggesting sugars may also function as a signal molecule in phosphorus-deficient soil conditions (Canarini et al., 2019). This proposed mechanism is supported by the exogenous application of sugars to roots and their subsequent suspension of growth at the root tip. Thus, primary metabolites initiate nutrient starvation pathways that modify root development.

Secondary metabolites also influence root architecture. For example, the exudation of strigolactones increases the development of dense root hairs and stimulates root hair elongation under poor soil phosphorus conditions (Haichar et al., 2014). Strigolactones are also released by plant roots that are associated with symbiotic arbuscular mycorrhizal fungi (AMF) to trigger hyphal branching of potential fungal symbionts prior to colonization (Haichar et al., 2014). These strigolactone-induced modifications to root hairs and hyphae generate an extensive network that can efficiently acquire the limited supply of phosphate ions and other essential substances in low nutrient environments.

Nutrient mobilization

Root exudates also help mobilize immobile nutrients, such as phosphorus, through chemical and biochemical reactions. The release of organic acids (e.g., malic acid, citric acid) dissolves metal-phosphate complexes by chelating metals (e.g., iron, aluminum) and solubilizing phosphate ions, which are then available to plants (Sasse et al., 2018). Protons exuded by roots alter the pH of the rhizosphere, which accelerates the chemical weathering of clay minerals and releases phosphate and other ions adsorbed to soil surfaces. Phosphatase enzymes are another mobilizing agent exuded from the roots of some plant species (e.g., *L. albus*). These enzymes can release available phosphate ions via the hydrolysis of certain organic phosphorus compounds—such as simple phosphomonoesters, phosphodiester and inositol hexakisphosphates—if in the proximity of the active phosphatase (Preece and Peñuelas, 2020). These foraging strategies, mediated by root exudates, assist plants in meeting their phosphorus nutrition requirements, in conjunction with the phosphorus obtained through any mycorrhizal associations.

Some root exudates can restrain the transformation of nitrogen forms into mobile species, such as nitrate. High nitrate levels in soil are undesirable because nitrate is susceptible to leaching and denitrification reactions that result in its loss from the soil-plant system. One strategy exhibited by some plants, like sorghum (*Sorghum* sp.), is to release root exudates that prevent the microbial transformation of ammonium into nitrate via ammonia and nitrite oxidation (Haichar et al., 2014). These biological nitrification inhibitors released in root exudates, such as methyl 3-(3-hydroxyphenyl) propionate, sorgoleone, and brachialactone, hold promise for restraining the nitrate-forming reactions in soil, as well as their production of nitrous oxide, a greenhouse gas. Currently, genes capable of producing nitrification inhibitors are being incorporated into commercial cultivars of wheat to improve nitrogen use efficiency and prevent nitrate loss through leaching or denitrification (Subbarao et al., 2021). Future use of this technology should result in improved crop performance, reduced nitrate pollution in waterways, and lower nitrous oxide emissions from cultivated fields.

Microbial selection

Root exudates can attract or repel soil microorganisms, which selects for microbial colonizers in the rhizosphere. This effect is driven by chemical gradients, created by the release of specific root exudates as signal molecules in the soil pore water. The proximity of microbial taxa to the release point of the root exudate (e.g., lateral root, root tip meristem) will determine their success in colonizing the growing root surface (Sasse et al., 2018). Microorganisms sense chemical gradients, and those that are mobile will move towards or against the strength of the signal via chemotaxis (Haichar et al., 2014). Once free-living microorganisms move into the rhizosphere or attach to the root surface, they can use the inorganic and organic root exudates for a variety of metabolic processes. Electron transport, respiration and other biological processes in microbial cells depend upon the energy, hydrogen protons, organic acids and carbon substrates in the root exudates. Free-living microorganisms may metabolize substrates exuded from the root into the soil pore water or acquire them indirectly, by cross feeding on the byproducts of microbial metabolism. Plants may deliberately target a particular free-living microorganism. For example, drought-stressed maize plants exude malic acid as a chemoattractant for *Bacillus subtilis*, a bacterium that can secrete osmolytes which maintain plant stomatal integrity and limit their water loss (Williams and de Vries, 2020).

Plants also use root exudates to select for symbiotic microorganisms, which are more intimately associated with roots since they can establish a mutualistic relationship that allows microbial colonization inside the root. To establish the mutualistic relationship, microorganisms and plants must communicate via chemical signals. The chemical signals from plants are transmitted through root exudation. Root-derived compounds, like strigolactones and flavonoids, are responsible for initiating the microbial symbiosis. These signals initiate a cascade of events that allow microorganisms like *Frankia*, rhizobia and mycorrhizal fungi to enter the root, proliferate and function in a way that is mutually beneficial to the plant host and the symbiotic microorganism (Haichar et al., 2014). The simplest mutualism is one in which the plant host provides carbon substrates, and the microbes supply the plant with growth-limiting nutrients. There is evidence that symbiotic plant-microbial relationships improve plant defenses, as discussed in the next section.

Plant defense

Mycorrhiza, the symbiotic relationship between plant roots and fungi, improves plant defenses through physical and biochemical means. The extensive hyphae growing on and around the root surface can function as a physical barrier that prevents pathogens from infecting roots. Second, mycorrhizal fungi can modify root metabolism and root exudate composition to protect the plant host from pathogens. These effects were shown for tomato plants (*Solanum lycopersicum*) that had a 108% lower rate of root penetration by root-knot nematodes (*Meloidogyne incognita*) when 79% of the root surface was colonized by AMF than when no AMF were present (Vos et al., 2012). Furthermore, root exudates collected from the AMF-colonized tomato plants were able to briefly paralyze the nematode pathogens. Thus, these symbiotic relationships initiated by root exudates are able to defend the plant from pathogenic attack via mycorrhiza-induced resistance.

Nevertheless, plants have an innate capacity for defense that does not rely upon the mycorrhizal symbiosis. For instance, root exudates like indols, flavonoids, and other secondary metabolites exert an antimicrobial effect that can inhibit the growth of pathogenic microorganisms in the rhizosphere (Haichar et al., 2014). Extracellular enzymes are another way that plants defend against pathogens because enzymes can inactivate the cellular machinery that root pathogens use to enter the root. Enzymes and antimicrobial compounds can be released preemptively or upon attack. Additionally, hydrogen protons in root exudates can acidify the rhizosphere and make it an inhospitable environment for some pathogenic microorganisms. Consequently, root exudation itself can protect plants from infections that limit their growth and development.

Methods of root exudate characterization and analysis

Root exudates are an ephemeral and dynamic pool of substances that are continually produced and metabolized by rhizosphere microorganisms. This makes it challenging to collect sufficient exudates to monitor and track the atoms and compounds contained in root secretions. Several creative methods have been developed to improve our ability to collect root exudates, quantify their chemistry and evaluate their effects on plants and the root-associated microbes, as described in the next sections.

Root exudate characterization

Characterizing root exudation by plants is crucial to understanding their intrinsic composition during the plant's lifespan, as influenced by plant physiology. Furthermore, we lack information about how abiotic and biotic factors affect the root exudation rate and concentration of the various compounds of interest within this complex mixture. Root exudates are generally collected from hydroponic systems, where plants are grown in a nutrient solution with minimal physical support (Williams et al., 2021). At the time of sampling, the entire root system is removed from the hydroponic system and soaked in fresh nutrient solution for a period of time to solubilize root exudates for analysis. However, many factors influence root exudation in hydroponic solutions, including the hydroponic design (reservoir vs. ebb and flow system, free root vs. inert substrate) and the aeration, pH and sterility of the nutrient solution (Oburger and Jones, 2018). In addition, the spatial scale of analysis needs to be considered, to understand whether root exudates will be collected from the entire root system or specific root regions (e.g., with split root systems or exudation traps; Oburger and Jones, 2018). Another challenge with hydroponic methods is that a solution-based system is unlike a natural soil environment and lacks the physicochemical and biological stimuli that prompt plant roots to release exudates. However, collecting root exudates from soil is complicated by the fact that most root exudates are transient and rapidly metabolized by rhizosphere microorganisms.

Researchers have the option of growing plants in natural soil environments before transferring them into a hydroponic system. There are several ways to obtain root exudates in this process. One of the most common is to carefully remove intact plants from a soil container, rinse the root system and transfer the roots into a nutrient solution, assuming that any root exudates that are collected in the solution represent the plant response in soil (Williams et al., 2021). This technique requires substantial disturbance of the root system during root washing. An alternative is to use a modified soil container known as a rhizobox, which can physically segregate part of the root system for precise sampling of root exudates (Pantigoso et al., 2021). We still need innovative strategies that allow plants to grow in realistic soil environments that give us access to the root system for the simple collection of root exudates.

Once root exudates are collected, the solution is prepared for analysis. Normally, filtration or centrifugation are required to remove root materials, microbial cells and other biological debris that would interfere with root exudate analysis (Oburger and Jones, 2018). This treatment purifies the extract, but the resulting solution generally contains a small concentration of exudates. The next step involves freeze-drying or rotary evaporation to concentrate the inorganic and organic solutes. These preparatory steps are needed to preserve the sample quality and ensure sufficient analyte for chemical assessment.

Characterization of the root exudates relies on advanced instrumentation, including high pressure liquid chromatography, ion chromatography, gas and liquid chromatography combined with tandem mass spectrometry, and nuclear magnetic resonance (Oburger and Jones, 2018; Sun et al., 2021). It seems impossible to get a complete analysis of all root exudates with a single instrument. Ion chromatography is suitable to characterize the polar root exudates (e.g., inorganic ions, amino acids, proteins), while gas chromatography is appropriate for the analysis of volatile organic exudates, gaseous molecules and primary metabolites. The chemical composition of dissolved secondary metabolites can be quantified with liquid chromatography or nuclear magnetic resonance spectroscopy. Thus, a sequential approach using several analytical methods is necessary to fully characterize root exudates.

Analysis of root exudate effects

Innovative techniques have been developed to assess the response of plants and the soil microbiome to root exudates. Applying synthetic exudates to bare soil and measuring the soil microbial response is one way to accomplish this objective (Sun et al., 2021). Although this does not reflect the actual exudates released from roots and it ignores the influence of the physical root structure on soil microorganisms, this approach can isolate the effects of specific exudates or cocktail of exudates on soil microbial processes in a realistic environment. An incisive technique to evaluate the effects of root exudates involves knocking out genes that are known to be important for root exudate production. Gene knockout procedures are often used to assess the direct effect of root exudates on soil pathogens, as well as the ability of these root exudates to illicit biocontrol responses by antagonistic organisms (Vives-Peris et al., 2020; Sun et al., 2021). However, these methods are often tested *in vitro* without soil, which obscures our understanding of root exudate processes occurring in natural soil environments. Most studies that use the gene knockout approach involve *A. thaliana*, a model organism that is simple to grow and has a fully sequenced genome. Relying on one plant species will naturally limit our understanding of root exudation, and this should be considered when interpreting root exudate effects on the rhizosphere.

During the past decades, isotope technology has revolutionized our knowledge of root exudation and its effects, especially regarding soil carbon and nitrogen dynamics. Typically, plants grown in soil are exposed to ^{13}C — CO_2 , which is fixed through photosynthesis and used by the plant to produce ^{13}C -root exudates. Root exudates can also be labeled with ^{15}N by exposing the plant to ^{15}N -nitrogen compounds via plant stem infiltration, leaf tip feeding or foliar application. Isotope tracing makes it possible to follow the movement of labeled compounds from shoots into the root tissues, and then track the quantities of labeled root exudates that are released, absorbed and metabolized by soil microorganisms before any tracer remaining in the lysed cellular debris enters the soil organo-mineral pool (Pett-Ridge and Firestone, 2017). We can also quantify the proportion of root exudates that are leached from the soil-plant system as ^{13}C -dissolved organic carbon and ^{15}N -dissolved organic nitrogen or lost as gaseous products like $^{13}\text{CO}_2$, $^{13}\text{CH}_4$ and $^{15}\text{N}_2\text{O}$. Such work improves our understanding of the transport and fate of root exudates in realistic soil environments, as well as the direct contribution of root exudation to greenhouse gas emissions. If the soil microbial biomass is sufficiently enriched with ^{13}C or ^{15}N , stable isotope probing is possible (Pett-Ridge and Firestone, 2017). This method would involve sequencing labeled nucleic acids or proteins to determine which microorganisms were preferentially metabolizing the root exudates and their subsequent activity. Inevitably, the carbon and nitrogen isotopes in soil pools may also come from other sources besides root exudates, such as from mucilage and dead root tissue. Nevertheless, isotope technology is an effective tool to resolve the fate of root-derived carbon and nitrogen, including root exudates.

Isotope tracing methods are limited by the destructive soil sampling at some point during the plant growth. This means that each sample is a ‘snap-shot’ of the root exudation and microbial responses at a particular point in time. To avoid the issues associated with repeated discrete sampling, researchers can label plants with radioisotopes (i.e., ^{14}C) instead, and use imaging technology like autoradiography to analyze the fate of root exudates (Oburger and Jones, 2018). This method enables continuous monitoring and assessment of the spatiotemporal distribution of root exudation in the short-term. However, as ^{14}C will be present in both root exudates and the root itself, it can sometimes be difficult to delineate the fate of root exudates in the soil environment from the physical root system of the plant. As such, the resolution of such images can pose a challenge in their interpretation. Radioisotope imaging also causes some soil disturbance when the intact root-soil system is placed in the imaging device. This experimental bias can obscure the findings, which is why radiography images of soil-root systems must be interpreted with caution.

Zymography is another imaging method used to measure extracellular enzyme activities in the rhizosphere. This is done by placing a substrate-loaded agar(ose) gel in the root-soil system. When roots come into contact with the gel, the extracellular enzymes released from the roots will hydrolyze the substrate and this appears as a color change on the gel (Spohn et al., 2013; Sanaullah et al., 2016). Similarly, specifically treated membranes or agar(ose) gels loaded with dyes can be placed in the rhizosphere to detect changes in pH and ion concentrations caused by root exudation. Fluorescence imaging is another way to visualize root exudation and the impact of specific root exudates on microorganisms that emit fluorescent light in the rhizosphere (Sun et al., 2021). However, these imaging methods measure rhizosphere effects rather than that of specific root exudates. Additionally, such methods are often performed at discrete points in time, though recent developments have substantially improved their temporal resolution to near-continuous measurements, like time-lapse zymography (Guber et al., 2021). Thus, imaging techniques are best used in conjunction with other analytical approaches to properly interpret the effects of root exudates on rhizosphere processes.

Summary and outlook

Root exudation is a fundamental controller of plant-microbial functions in the rhizosphere. From their origin as photosynthates in leaves that are transported and transformed to bioactive substances in the roots, exudates are integral to plant growth and development. These exudates transform the oligotrophic soil around the root into a carbon- and nutrient-rich microenvironment with intense biological activity. If roots engineer the rhizosphere, then root exudates are the building blocks supporting a diverse community of free-living and symbiotic microorganisms that are directly responsible for maintaining plant productivity and health.

Root exudates are a broad class of substances that serve multiple functions for plants once they are secreted into the soil environment. However, future discoveries about root exudates will require us to improve the methodologies for their collection from realistic soil environments, along with continuous sampling protocols and integrated analytical platforms that can quantify the range of inorganic and organic substances that roots exude into the rhizosphere. Information on the activity of root transporter systems could be a helpful indicator of secondary metabolite and extracellular enzyme movement from the root to the surrounding environment.

Improved methodologies are essential for characterizing the breadth of root exudates that exist, but innovative strategies are also required to grasp the scale of root exudate effects on the rhizosphere. This includes microRNA (miRNA), which has garnered immense interest during the past years with recent discoveries on their potential ability to silence microbial genes, but whose full impact on microbe-plant interactions remains to be assessed. Understanding the response of microbes to exuded miRNA with incisive studies is key to unlocking the extent of their function in regulating microbial activity in the rhizosphere. We also should be able to document the response of rhizosphere microorganisms to root exudation as a whole with advanced techniques like RNA and protein stable isotope probing. These promising methods are still in their infancy for understanding nutrient transfers and other processes in the plant-microbial system, and merit further use.

Better understanding of root exudation in agricultural crops would not only reveal much about plant tolerance to abiotic stresses, their ability to acquire essential nutrients and capacity for self-defense against growth-limiting biota, but could also lead to microdosing of pesticides and fertilizer rather than uniform field applications. Additionally, further research into the root exudate profiles that regulate microbial metabolism could identify root exudates that either trigger (e.g., labile carbon substrates) or impede (e.g., biological nitrification inhibitors) greenhouse gas production. In the face of climate change, these findings could help us to one day engineer crops that sequester fixed carbon in and mitigate nitrous oxide emissions from cultivated soils. Such developments are consistent with the goals of precision agriculture and align well with global initiatives aiming to achieve food security, protect the agroenvironment and stabilize rural income in sustainable agroecosystems, now and in the future.

Abstract

Roots assemble a diverse community of soil microorganisms in their rhizosphere, the biologically active microenvironment that exists between the root surface and the bulk soil. Roots and their rhizobiome, which include root-associated and endophytic microorganisms, produce and respond to chemical signals. This cross-talk involves the exchange of hundreds of metabolites that alter plant growth, development and defense responses at genetic, cellular, physiological and morphological levels. This allows the root-rhizobiome partners to engineer their shared rhizosphere and optimize its physical, chemical and biological properties for their joint benefit and survival.

Key points

- Plant roots associate with a diverse community of soil bacteria, fungi and archaea to create a rich, biologically-active rhizosphere.
- The rhizobiome consists of microorganisms that live on or around the root surface, as well as endophytes that colonize the root epidermis, cortex and vascular tissues.
- Interactions in the root-rhizobiome result from the exchange of chemical signal molecules, which are produced and responded to by both biological partners.
- The rhizobiome acts as an early warning system of environmental stresses, leading to phenotypic plasticity in plant root and shoot development, or the upregulation of protective functions like induced systemic resistance and antioxidant production. Plants benefit when their rhizobiome senses changes in the soil environment.
- Root-rhizobiome interactions have considerable potential for sustaining food and fiber production systems.

Introduction

Plant roots occupy, and modify, the soil profile of vegetated land. Root-associated soil between the rhizoplane and the bulk soil is referred to as the rhizosphere. Constant interactions between plant roots and soil biota make the rhizosphere a zone of intense biological activity. However, the rhizosphere is also spatially variable. Plant roots extend vertically to a depth of a few to hundreds of centimeters, depending on the depth of the soil profile and the plant species. Thale cress (*Arabidopsis thaliana*), a model organism in plant biology research, has a primary root that reaches a depth of 6.5 cm with about 10 lateral roots extending from the primary root, the longest being nearly 2 cm, after 9 days (Aceves-García et al., 2016). Perennial tree and vine crops like apple (*Malus domestica*), peach (*Prunus persica*), Asian pear (*Pyrus pyrifolia*), grape (*Vitis* spp.) and kiwifruit (*Actinidia deliciosa*) produce woody and fine roots that explore 55–99% of the soil volume to a depth of 1 m, based on cores taken within 2 m of the main woody stem in

established orchards (from 3 to 8 year old; Hughes et al., 1995). It is unlikely that areas in the soil profile are completely unexplored by roots, since the continual turnover of fine roots suggests the absence of roots is only temporary.

Microorganisms that inhabit plant roots and the rhizosphere are known as the rhizobiome. Plant root-microbial interactions have existed for millennia and coincide with the appearance of terrestrial plants on Earth, about 450 million years ago. The common symbiosis pathway, a conserved molecular signaling pathway, is found in all terrestrial plants that interact with bacteria and fungi through rhizobial, actinorhizal and mycorrhizal fungal symbioses. As details of symbiotic plant-microbial interactions are covered in other chapters, they will not be repeated here. Rather, we focus upon free-living soil microorganisms that colonize plant roots and the rhizosphere to share carbon and other resources. The active recruitment of such microorganisms is most evident in young plant seedlings. For example, about 27% of the photosynthates allocated to the root system of spring rye (*Secale cereale*) were respired through root and microbial metabolism during early vegetative growth, and this declined to about 5–8% of photosynthates respired during the stem elongation and ear emergence stages (Remus et al., 2016). The microbial community benefiting from these photosynthates includes around 2500–3000 bacteria, 300–350 fungi and 50 ammonia-oxidizing archaea, based on the number of unique operational taxonomic units in the rhizosphere of *S. cereale* (Li and Wu, 2018).

Plant roots use photosynthates to build a deep, extensive system of structural roots that anchor the plant and help it find water, nutrients and interact with soil microorganisms. Upon reaching a favorable soil microenvironment, epidermal root cells behind the root tip differentiate to produce root hairs that send phytochemicals into soil pores. Dissolved and volatile chemicals attract soil biota towards the root. Communicating through chemical signals, plant root cells and free-living soil microorganisms interact in ways that are beneficial to one, if not both, of the organisms. Cooperative interactions in the rhizosphere give the rhizobiome more capacity than microorganisms in the bulk soil to solubilize inorganic phosphates, dissolve metal oxides, chelate trace metals and mineralize organic matter. The rhizobiome also produces plant growth promoting hormones (phytohormones) that control the extent of root growth. Furthermore, the rhizobiome often acts in a protective way, by directly inhibiting the growth of infectious plant pathogens and parasites, or by up-regulating the induced systemic resistance that defends plants from these and other harmful organisms.

This chapter explains how plant roots attract soil bacteria, fungi and archaea to the rhizosphere. We concentrate on the well-studied rhizobiomes of plants used as food and medicine, as forage for grazing animals, and that provide fibrous materials for textiles, buildings and energy. In this chapter, the rhizobiome is also considered to include microorganisms that penetrate the root epidermis and become resident as root endophytes. This is justified because the biological influence of root endophytes extends into the rhizosphere. Finally, we examine how plant roots and their rhizobiome engineer the soil matrix to create a favorable environment for their biological activities. We discuss the soil physical and chemical gradients that develop from the rhizoplane to the bulk soil through root-microbial interactions, with relevant examples.

Chemical signaling between roots and their rhizobiome

Like all living cells, plant root cells are aware of their surrounding environment. Roots respond in real time to cues from soil microorganisms and to conditions in the soil matrix. When an external signal molecule binds to a compatible receptor in the target root cell, it elicits a cellular response. The chemical signal received by a single root cell will be transmitted throughout the entire plant by cell-to-cell communication. This occurs because every plant cell is connected directly to neighboring cells via the plasmodesmata, a water-filled channel ≤ 50 nm in diameter that transfers intracellular mediator substances (ions and molecules up to ~ 500 Da in size) from one cell to the next. This means that the plant can use its entire cellular network to respond to a chemical stimulus. Consequently, plant growth depends upon the actual environmental conditions, and no two plants have an identical response. This gives rise to the phenotypic variation in plant communities, where genetically similar plants have unique shapes, sizes and productivity because they have adapted to live in a local microenvironment.

Root signals that attract compatible microorganisms to the rhizobiome

One of the ways that plants contend with environmental variation is by interacting with microorganisms. Signaling between plant roots and soil microorganisms was traditionally studied in the context of plant symbioses with rhizobial bacteria and mycorrhizal fungal but is now understood to be a widespread phenomenon involving diverse, non-symbiotic microorganisms that become part of the rhizobiome. Signaling processes are complex and multi-directional (Venturi and Keel, 2016). Three levels of cellular communication occur in the rhizosphere: (1) signaling from plants to microorganisms via small plant-secreted molecules, (2) signaling from microorganisms to plants, based on microbially-produced compounds that affect plant gene expression, root architecture, and plant defense responses, and (3) microbial intraspecies and interspecies signaling, which occurs mainly via quorum-sensing signal molecules that synchronize the growth and activity of the rhizobiome (Fig. 1).

Roots release soluble and volatile chemical molecules that are recognized by soil microorganisms. In the simplest cases, motile microorganisms in the soil pore water receive the chemical signal and respond by swimming towards the root, colonizing the root surface and multiplying in the rhizosphere. Maize (*Zea mays*) releases benzoxazinoids from their roots that causes the soil bacteria *Pseudomonas putida* to transcribe genes for benzoate catabolism and chemotaxis, increasing *P. putida* colonization of roots in wild-type maize compared to a modified maize cultivar that does not produce these compounds (DIMBOA-deficient bx1 mutant; Neal et al., 2012). Sessile microorganisms depend upon root-based signals to locate the closest plant root. When roots exude

Fig. 1 Known molecules and events involved in intra- and interspecies signaling among microorganisms and interkingdom signaling between microorganism and plants in the rhizosphere. The rhizosphere is populated by a diverse community of microorganisms, including rhizobia (bacteria), mycorrhiza (fungi), plant growth promoting bacteria and fungi (PGPR and PGPF), and nematodes. The interactions of these organisms with the plant are often beneficial. To coordinate their behavior and to control their growth and activity, these microorganisms produce a diversity of signals, among them quorum-sensing (QS) molecules such as N-acyl homoserine lactones (AHLs), diffusible signal factor (DSF), and diketopiperazines (DKPs), antibiotics at subinhibitory concentrations, phytohormone-like molecules, volatile organic compounds (VOCs), and, in the case of nematodes, specific pheromones (acaricides). These communication molecules can also function as interkingdom signals that elicit various effects on plant developmental processes and on local and systemic immune responses (i.e., ISR, induced systemic resistance; and SAR, systemic acquired resistance) and involve interactions with plant hormonal signaling via salicylic acid (SA), jasmonic acid (JA), and ethylene (ET). The plant recruits, shapes, activates and sustains its rhizobiome via the release of root exudates and signaling molecules. To recognize its associated rhizomicrobiome, the plant uses dedicated pattern recognition receptors (PRRs) and presumably other as yet unknown receptors to detect particular microbe-associated molecular patterns (MAMPs) and likely the signals presented by the microorganisms. Recruitment of symbiotic rhizobia and mycorrhiza is initiated by the exchange of specific plant signals (flavonoids and strigolactones, respectively) and microbial signals (Nod factors and Myc, respectively). Signal exchange is also involved in the attraction and colonization of roots with PGPR and PGPF. In addition to hosting beneficial microorganisms as guards, the plant also uses confusion and inhibition strategies (e.g., QS mimicry and quenching) to ward off harmful microorganisms. From Venturi V and Keel C (2016) Signaling in the rhizosphere. *Trends in Plant Science* 21: 187–198. doi: 10.1016/j.tplants.2016.01.005.

strigolactones, a group of phytohormones, the nearby arbuscular mycorrhizal fungi grow longer, branching hyphae before they form the appressorium or hyphopodium, specialized cells used by the fungus to penetrate the plant root. Successful fungal colonization begins with physical contact between the appressorium and the root surface, followed by detection of plant chemicals like hexadecanoic acid in the cutin of root cells, cyclic adenosine monophosphate (cAMP) and ethylene.

The rhizobiome recognizes plant signals, but it also synthesizes compounds that elicit a plant response. Volatile organic compounds released by the rhizobiome include natural products that act as antimicrobials, while promoting plant growth, inducing plant disease resistance and supporting signal transduction pathways that allow plants to quickly respond to natural gradients in light, water, nutrients and other vital resources. The main benefit of volatile organic compounds, relative to water-soluble chemicals, is their enhanced ability to permeate cell membranes and the ease with which they diffuse through the air-filled pores in soil. In raspberry

The inhibition rate in vitro was between 0% and 100% inhibition, or not determined (ND).

Adapted from Zhang XY, Gao ZF, Zhang XX, Bai WB, Zhang L, Pei HB, and Zhang YJ (2020) Control effects of *Bacillus siamensis* G-3 volatile compounds on raspberry postharvest diseases caused by *Botrytis cinerea* and *Rhizopus stolonifera*. *Biological Control* 141: 104135. doi: 10.1016/j.biocontrol.2019.104135.

(*Rubus idaeus*), there was up to 100% growth inhibition of the fungal pathogens *Botrytis cinerea* and *Rhizopus stolonifer* by two volatile organic compounds produced by the root-associated bacteria *Bacillus siamensis*, namely 2, 6-di-tert-butyl-4-methylphenol (BHT) and 2,4,2,4-di-tert-butylphenol (2,4-DTBP; Zhang et al., 2020; Table 1). Besides inducing plant defenses for better resistance to resist diseases, pests and abiotic stresses, the rhizobiome also produces growth-promoting substances, described in the following sections.

Finally, bacterial members of the rhizobiome exchange quorum-sensing molecules to control their community composition and regulate growth. In general, these molecules help bacteria to synchronize their gene expression in response to cell density, a process known as quorum sensing. One class of quorum-sensing molecules are the N-acyl homoserine lactones, produced by proteobacteria in the rhizosphere. The N-acyl homoserine lactones initiate biofilm formation, causing bacterial cells to aggregate on the root surface. Next, the colony produces extracellular polymeric substances (exopolymers) that protect it from desiccation and other environmental stresses. Production of N-acyl homoserine lactones and other quorum-sensing molecules (e.g., diffusible signaling factors that are cis-2-unsaturated fatty acids, auto-inducing peptides) also influence plant gene expression, induce systemic resistance, and affect plant growth and development. However, plant roots do not passively accept bacterial colonizers. Plants can biosynthesize inhibitory substances that prevent bacteria and fungi from living on their roots. Some of these compounds are phenolics, including benzoates, phenyl propanoids, stilbenes, flavonoids, gallotannins, proanthocyanidins and coumarins, as well as terpenes (monoterpenes, sesquiterpenes, diterpenes and triterpenes), quinones and organosulfur compounds. Secreting these inhibitory substances allows plants to control quorum sensing and biofilm formation on their roots, stems and leaves (Ta and Arnason, 2016). This is an example of cross-talk (exchange of signal molecules) that is characteristic of root-microbial interactions in the rhizosphere.

Root endophytes

Often originating from the soil, root endophytes are microorganisms that become resident in plant root tissues and live there for at least part of their life cycle, without causing disease. Bacteria root endophytes are common in the intercellular space of roots, presumably because there is enough space for their growth plus access to abundant water, carbohydrates, amino acids and inorganic nutrients. In the early stages of colonization, bacteria root endophytes are first observed in root hairs, and subsequently in the root cortex. For example, grape roots inoculated with *Burkholderia* sp. supported the bacterial endophytes in their cortical cells, endodermis and xylem vessels (Compant et al., 2005); colonization was greatest in the primary and secondary roots, and at the base of lateral roots and root tips. Fungal endophytes are routinely isolated from the roots of apparently healthy and vigorous plants. They have regularly septate hyphae with variable texture (translucent, glassy) and color (from lightly to darkly pigmented). The hyphae grow on, in, and in between cells of the epidermis, cortex, and sometimes in the vascular tissue of roots. Virtually every terrestrial plant in the world has fungal root endophytes. In contrast, the archaea root endophytes are an under-investigated group that were detected in the rhizosphere of crops by culture-independent metagenomics technologies. To date, no root-associated archaea endophyte has been isolated and cultured, which is a gap in our scientific knowledge.

Endophytes gain access to plant roots through active and passive mechanisms (Fig. 2). After they attach to the rhizoplane, bacterial endophytes move along the root surface and seek potential entry into the root. Wounds and cracks, as well as openings where root hairs or lateral roots emerge, are the main points where bacterial endophytes enter the root. Furthermore, some bacterial endophytes secrete cell wall cellulolytic enzymes such as cellulases, xylanases, pectinases, and endoglucanases to weaken the root cell wall and enter the root. During the early stages of rice root colonization, the endophytic diazotrophic bacterium *Gluconacetobacter diazotrophicus* expressed genes that deactivated oxidative stress and upregulated the antioxidant response (Alquéres et al., 2013). This suggests a well-developed stealth strategy that allows the bacterial endophyte to penetrate the root without activating a plant defensive response. Once established, bacterial endophytes support plant growth by producing phytohormones, increasing nutrient acquisition and improving plant resilience to abiotic and biotic stresses. On balance, this makes root endophytes beneficial members of the rhizobiome.

Ecological interactions of roots and their rhizobiome

The co-evolution of plants and microorganisms allows for multiple interactions between these biological partners. From an ecological perspective, the interactions can be negative for both organisms (competitive, antagonistic), positive for both organisms (mutualistic, symbiotic), or positive for one and negative for the other (commensal, pathogenic). Interactions change the physiology and morphology of the plant host and its microbial guests, altering the function of one or both partners.

The rhizobiome is populated by microbial cells that reached the root by chance or in response to signal molecules, also referred to as infochemicals, that are released from the plant root and guide microorganisms towards the root surface. Upon colonizing the plant root, the antagonistic microbe may produce specialized molecules that repel other microorganisms from the root. For instance, the root nodule tissue of field-grown alfalfa (*Medicago sativa*) harbors an accessory bacterial community of non-Rhizobiales members from the phyla Actinobacteria, Bacteroidetes, Firmicutes and Proteobacteria, which tend to be more abundant on older nodules (Hansen et al., 2020). Some dominant bacteria inhabiting the nodule are cooperative partners (e.g., *Paenibacillus* sp. and *Pseudomonas* sp.). However, the Gram-positive aerobic bacteria *Brevibacillus brevis* produces antibiotics (novel

Fig. 2 Passive and active pathways leading to microbial colonization of the endosphere of plant roots.

gramicidin-family metabolites called brilacidin) that inhibit the growth of other bacteria (Hansen et al., 2020). Colonization of root tissues by antibiotic-producing bacteria is significant because these antagonists will control the composition and functions of the rhizobiome. Hansen et al. (2020) interpreted the bacteria-bacteria antagonism to be a strategy that would protect nodules from an infectious bacterial pathogen; thus, antagonism in the rhizobiome could be important to preserve biological N₂ fixation, a critical function in alfalfa.

An example of a mutualistic interaction is when a root-associated microorganism alters the root physiology and morphology for the benefit of the root and the rhizobiome. Mutualistic microorganisms can use hormonal, genetic and regulatory mechanisms to change the root architecture and anatomical phenotype of their plant host. Hormonal effects occur when the microorganism secretes phytohormones, or when it produces secondary metabolites that control hormonal pathways within the root. For instance, rice roots are longer when indole-3-acetic acid production is induced by *Azospirillum brasilense*, *Bacillus altitudinis* and *Klebsiella pneumoniae*, while more lateral roots grow when the cytokinins level is modulated by *A. brasilense*, *Phomopsis liquidambari* and *Rhizophagus irregularis* (Verma et al., 2022). Greater root mass, root thickness, length, and more lateral roots are produced when rice is colonized with *Rhizophagus irregularis* because the fungal partner modulates the expression of OsCYCLOPS1 and OsLRT1 genes, which regulate several phytohormones (auxin, cytokinins, abscisic acid and ethylene). These observations should encourage further study into the mutualistic interactions of roots and their rhizobiome.

Finally, plant roots are negatively impacted by pathogens, disease-causing organisms that are fungi, bacteria, protists, nematodes or viruses. Proliferation of root pathogens causes a range of symptoms, from mild impairment of root functions to plant death, depending on the severity of the infection. Plant constitutive and induced defense systems can partially control root pathogens, but the rhizobiome can also provide protection. Some antibiotics produced by the rhizobiome are effective against pathogens because they disrupt the cell wall and cell membrane structures, while inhibiting ribosomal biogenesis during pathogen cell division. Rhizobacteria like *Bacillus* spp. secrete extracellular enzymes such as chitinases, β -1,4-glucanases, proteases, cellulases and xylanases that inhibit the mycelial growth of fungal pathogens like *Botrytis cinerea*, *Fusarium oxysporum*, *F. solani* and *Rhizoctonia solani* (Dutta et al., 2022). By occupying the root surface and competing for water, Fe³⁺ and other nutrients, the rhizobiome may be able to indirectly displace root pathogens. Rhizobacteria also induce systemic resistance in plants through the jasmonate and ethylene signaling pathways. Furthermore, various rhizobacteria are known to increase the mRNAs encoding for phenylalanine ammonia lyase (PAL), the first key enzyme in the phenyl propanoid pathway that biosynthesizes phenolics and phytoalexins, as well as upregulating salicylic acid production, another pathway for induced systemic resistance in plants (Dutta et al., 2022). These examples illustrate the potential of root-rhizobiome interactions to reduce the severity of plant diseases caused by pathogens.

Physical and chemical gradients from the rhizoplane to bulk soil

The rhizosphere, starting at the rhizoplane and ending at the bulk soil, has unique physical and chemical properties. These characteristics are the result of the growth and biological activity of the roots and their rhizobiome. However, the rhizosphere is spatially variable, depending upon the plant species and its root architecture. Furthermore, the magnitude of root-rhizobiome activity is determined by the plant growth stage, soil edaphic factors and environmental stresses. The next sections explain how root-rhizobiome interactions create a distinctive rhizosphere that has unique physical and chemical properties from the rhizoplane and the bulk soil.

Physical gradients

Roots extend vertically and expand horizontally through pores in the soil matrix, but the force of a growing root is sufficient to alter the physical environment, making it better suited for anchoring the plant and acquiring resources. Roots seek a path of least resistance, which encourages growth in the existing cracks and fissures, although bypassing rocks and compacted layers. However, roots can also create space by deforming the friable soil mass. This occurs because roots exert pressure that displaces the soil particles when they enter soil pores that are smaller than the root diameter. The maximum axial root growth pressure ($\sigma_{\max}$) is 200–1300 kPa for various species and genotypes of annual crops (Hosseini et al., 2019). We expect larger primary roots and lateral roots with a smaller diameter to exert a similar amount of axial root growth pressure because the force needed to push aside soil particles is proportional to the root diameter. Root hairs are unlikely to modify soil physical properties due to their small size (about 15 μ m diameter and $\leq$ 1 mm long). Root elongation rates depend on the cell turgor, cell wall extensibility and cell wall pressure of the roots, each of which responds to environmental conditions.

Soil conditions are not always favorable to root growth. Compacted soils and degraded soils often have high mechanical impedance to root penetration. Plants respond by growing shorter, thicker roots. This occurs because ethylene, a plant hormone and gas released from root tissue, accumulates around roots in a compacted soil. Rice (*Oryza sativa* L.) roots exposed to a high ethylene concentration will produce other plant hormones, principally auxin, which reduces root elongation, and abscisic acid that promotes radial cell expansion (Huang et al., 2022). Drought is another barrier to root growth since it creates osmotic stress, which affects root cell turgor, and increases the soil mechanical strength because water is held more tightly to the soil matrix. One of the ways that roots adapt to penetrate dry, hard soils is through their rhizobiome. For example, when maize was colonized by the fungal root endophyte *Piriformospora indica* (basidiomycete of the Sebacinaceae family), it could produce at least double the maximum axial root growth pressure (from 505 to 780 kPa) than without the fungal partner (186–344 kPa; Hosseini et al., 2019).

Water acquisition by plant roots and their rhizobiome

Plants get most of their water from soil, through their roots. Due to their diverse morphology, roots vary in their ability to acquire water from soil. In general, younger, finer roots have greater water uptake rates per surface area than mature roots. Still, it is challenging to acquire plant-available water from the soil matrix. Sometimes the soil becomes so dry that it reaches the permanent wilting point for plants. Once a plant wilts and cannot recover its turgidity after 12 h in a fully watered soil, it is considered to have permanently wilted. Normally, the soil still contains water at the permanent wilting point, but the water is adhering too tightly to soil particles to be extracted by the plant, or the water is within micropores ($<10\ \mu\text{m}$ in diameter) that are not accessible to plant roots (i.e., the smallest root hairs are about $15\ \mu\text{m}$ in diameter). Thus, roots cannot always obtain enough soil water to fulfill plant metabolic needs.

Plants rely on the rhizobiome to overcome soil water deficits. Fungal root endophytes are particularly interesting in this regard. After the fungus colonizes the plant root, it grows long branching, filamentous hyphae (from 3 to $30\ \mu\text{m}$ in diameter) that extend into the soil pores. The smallest hyphae can enter micropores of about $2\ \mu\text{m}$ diameter that are inaccessible to plant roots and root hairs (Kakouridis et al., 2022). Water and solutes in the micropore then move along the surface of the fungal hyphae through capillary action, towards the plant root. Fungal hyphae often connect multiple plants. For example, hydraulic redistribution of water from pine trees (*Pinus ponderosa*) to their seedlings was facilitated by the hyphae of ectomycorrhizas (mostly *Rhizopogon* sp.), which transferred about 15% of the water required for seedling growth (Warren et al., 2008). Another way that fungal hyphae change soil hydraulic properties in the rhizosphere is by promoting macroaggregate formation. Structurally, a macroaggregate is an agglomeration of microaggregates ($<0.25\ \text{mm}$ in diameter containing clay, metal oxides and bacterial debris) that are held together with sand, silt and organic matter by fungal hyphae. A rhizosphere with more macroaggregates also has more macropores for root growth and that conduct water towards the roots. When switchgrass (*Panicum virgatum*) was inoculated with mycorrhizal fungal (*Piriformospora indica*), the greater porosity allows roots and fungal hyphae to partially fill macropores, decreasing the saturated hydraulic conductivity and allowing them to access more water in saturated and unsaturated soils (Marcacci et al., 2022). These examples of fungal-mediated physical changes in the rhizosphere soil have a direct impact on water acquisition by plants.

There are two additional ways that fungal partners increase the water supply to plants. Fungal hyphae exude hundreds of metabolites, including carbohydrates and polyols (9% of the total number of metabolites identified), amino acids and amines (43%), nucleic acids (10%), organic acids (21%), fatty acids (1%), homologs (5%), phosphate esters (9%), phytohormones (1%), and others (1%) (Luthfiana et al., 2021). Some of these substances will attract water, similar to plant mucilage, and may help to retain water in the rhizosphere during dry periods. Finally, fungal hyphae can directly transfer water through cell-to-cell interactions, from soil to plants. Slender wild oat (*Avena barbata*) colonized by *Rhizophagus intraradices* relied on the fungal hyphae to bridge air gaps, penetrate small pores and access water that was inaccessible to roots. Nearly 35% of transpired water was directly transferred from the fungal partner to the plant through cellular transport and via an extracytoplasmic pathway, along the external surface of the fungal hyphae (Kakouridis et al., 2022). This further confirms the importance of root-fungal interactions to maintain plant productivity in dry environments.

Chemical gradients

Rhizosphere soil pH

The rhizosphere is generally more acidic than the bulk soil (Fig. 3). When roots absorb nutrient ions from the soil water, they release a counter-ions into the environment. Uptake of positively charged ions such as NH_4^+ , K^+ , Ca^{2+} , Mg^{2+} and micronutrients like Fe^{2+} , Mn^{2+} , Cu^{2+} and Zn^{2+} is accompanied by the release of a proportionate amount of H^+ into the soil solution. Root hairs have epidermal cell membranes containing proton pumps (H^+ ATPases) that use ATP as an energy source to pump H^+ out of the cell and into the soil, against their electrochemical gradient. These proton pumps create a strong electrochemical gradient with a high concentration of protons and a strong positive charge outside of the cell, and a low concentration of protons and relatively negative charge inside of the cell. The electrochemical gradient causes cations to diffuse to the root hairs, and they may enter the root through passive diffusion (e.g., through porins) or active transport via carrier proteins (i.e., against a concentration gradient). Electrochemical and concentration gradients are also important for plant uptake of negatively charged ions like NO_3^- , H_2PO_4^- , SO_4^{2-} , Cl^- and MoO_4^{2-} . Plants also release anions like OH^- and HCO_3^- to maintain the electrical neutrality of the anion uptake process. Consequently, the area closest to the root surface has a distinct pH from the rest of the rhizosphere, and the bulk soil (Taylor and Bloom, 1998).

Roots and their rhizobiome also secrete organic acids that acidify the rhizosphere. Organic acids contain one or more carboxylic groups. Root exudation of organic acids can acidify the rhizosphere from near neutrality (around pH 7) to pH 4–5, depending upon the type and quantity of organic acids secreted into the rhizosphere. Roots produce acetic, citrate, malate, oxalate, shikimate and malonate acids, among others, with concentrations of 5–50 mM in the root cell vacuoles being as much as 10-fold greater than organic acids concentration in the cytosol, depending on the plant species and growing conditions (Sandnes et al., 2005). Monocarboxylic acids are the most common organic acid produced by roots, followed by the di- and tri-carboxylic acids. Furthermore, organic acids are released by the rhizobiome and from the decomposition of organic matter and plant residues in soil. However, roots and the rhizobiome often secrete $>1\ \text{mM}$ of organic acids in the rhizosphere, which is about two orders of magnitude greater than the bulk soil with $<0.01\ \text{mM}$ of soluble organic acids (Sandnes et al., 2005). These levels of organic acids in the rhizosphere are of biological importance to roots and their rhizobiome.

Fig. 3 Root surface pH profiles along the primary root axis of 4-d-old maize seedlings. The length of the primary root is indicated by the black bar, above the x-axis. pH readings were taken at multiple distances (in mm) at the root surface (open symbols) and in the bulk solution (closed symbols). Maize seedlings were grown in hydroponic solutions with zero nitrogen, 50 μM $\text{Ca}(\text{NO}_3)_2$, 50 μM $(\text{NH}_4)_2\text{SO}_4$ and 100 μM NH_4NO_3 . The pH is always lower at the root surface than in the bulk solution, confirming that the rhizosphere tends to be acidic, relative to the surrounding soil. From Taylor AR and Bloom AJ (1998) Ammonium, nitrate, and proton fluxes along the maize root. *Plant, Cell & Environment* 21: 1255–1263. doi: 10.1046/j.1365-3040.1998.00357.x.

Organic acids in the rhizosphere are involved in soil weathering, which chemically transforms rocks into mineral forms. For example, plagioclase feldspar ($\text{CaAl}_2\text{Si}_2\text{O}_8$) is hydrolyzed to kaolinite clay ($\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4$) in the presence of carbonic acid (H_2CO_3) in an acidic environment.

Acidic conditions also favor oxidation reactions. The dissolution of olivine (a ferromagnesian silicate, Fe_2SiO_4) in the presence of carbonic acid produces dissolved iron, carbonate, and silicic acid (H_4SiO_4).

When oxygen is present, the dissolved iron is quickly converted to hematite, Fe_2O_3 :

These reactions release soluble Ca^{2+} and Fe^{2+} , which are essential nutrient ions for biological activity. Such reactions, facilitated by organic acids, assure the root-rhizobiome of a steady supply of ions that are released from minerals, including K^+ , Mg^{2+} , Mn^{2+} , Cu^{2+} and Zn^{2+} .

Organic acids are also involved in the dissolution of phosphates that precipitated with calcium, iron and aluminum in soil. Calcium phosphates such as dicalcium phosphate ($\text{CaHPO}_4 \bullet 2\text{H}_2\text{O}$), octacalcium phosphate ($\text{Ca}_8\text{H}_2(\text{PO}_4)_6 \bullet 5\text{H}_2\text{O}$) and hydroxyapatite ($\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$) are the most common of the stable, insoluble crystalline phosphate forms in alkaline soil. Although calcium phosphates are sparingly soluble in water, all dissolve in acids, including organic acids. In acidic soils, phosphate ions precipitates with iron, often strengite ($\text{FePO}_4 \bullet 2\text{H}_2\text{O}$) and aluminum as wavellite [$\text{Al}_3(\text{PO}_4)(\text{OH})_3 \bullet 5\text{H}_2\text{O}$] and variscite ($\text{AlPO}_4 \bullet 2\text{H}_2\text{O}$). Furthermore, phosphate becomes chemisorbed to the hydroxides and oxides of iron and aluminum in soil. Organic acids chelate with iron and aluminum (hydr)oxides, which either replace phosphates in sorption sites or prevents the ions from binding with the iron and aluminum.

Roots control the concentration and composition of organic acids secreted into the rhizosphere based on their genetics and environmental factors, like soil acidity, the presence of insoluble minerals, phosphorus deficiency and metal toxicity. More phosphate is solubilized with the root-produced tricarboxylic acids (citric and tartaric acids) than dicarboxylic acids (maleic and fumaric acids), followed by monocarboxylic acids (oxalic and acetic acids; Sindhu et al., 2022). Rhizobiome strains of *Bacillus* secrete a mixture of lactic, isovaleric, isobutyric and acetic acids that contribute to mineral weathering. Phosphate-solubilizing bacteria in the genera *Burkholderia*, *Cronobacter*, *Curtobacterium*, *Enterobacter*, *Massilia*, *Pantoea*, *Pseudomonas* and *Ralstonia* release organic acids like glycolic, oxalic, malonic and succinic acids. Rhizosphere-compatible fungi such as *Alternaria*, *Aspergillus*, *Fusarium*,

Table 2 Chemical forms of organic acids in the rhizosphere that are biosynthesized by plant roots or by soil microorganisms.

Aliphatic carboxylic acids			Aromatic carboxylic acids	Miscellaneous carboxylic acids	Substituted acids
Monocarboxylic	Dicarboxylic	Tricarboxylic	p-Coumaric acid	Phthalic acid	1-aminocyclopropane-1-carboxylic acid
Acetic acid	Fumarate	Aconitic acid	Ferulic acid	Shikimic acid	2,4-dichlorophenoxyacetic acid
Butyric acid	Maleic acid	Citric acid	Gallic acid		2,4,5-trichlorophenoxy acetic acid
Formic acid	Malic acid		p-hydroxybenzoic acid		Absciscic acid
Lactic acid	Malonate		Protocatechuic acid		Gibberellic acid
Propionic acid	Oxalate		Salicylic acid		Indole-3-acetic acid
Pyruvic acid	Succinate		Sinapic acid		
Valeric acid	Tartarate		Syringic acid		
			Vanillic acid

Helminthosporium and *Penicillium* also produce oxalic, maleic, succinic, citric, and fumaric acids that release the precipitated and sorbed phosphates from the mineral phase into soil pore water (Table 2). The cooperative phosphorus-solubilizing activity of roots and their rhizobiome improves their uptake of phosphates, which are essential for the growth and survival of all living organisms.

Redox conditions in the rhizosphere

The activity of roots and their associated rhizobiome is affected by the availability of molecular oxygen (O_2). The O_2 concentration from the root surface to the bulk soil depends upon the balance between O_2 consumption from biological respiration, and the amount of O_2 that diffuses into the rhizosphere from the atmosphere and O_2 -rich soil pores. Biological respiration in the rhizosphere usually relies on aerobic metabolism of carbon substrates with O_2 as the dominant electron acceptor in the roots and rhizobiome. If the rhizosphere has a low O_2 concentration because the pores are filled with water (i.e., O_2 diffuses more slowly through water-filled pores than through air-filled pores), the microorganisms might switch from aerobic to anaerobic respiration. In anaerobic respiration, microorganisms will use alternative terminal electron acceptors in the respiratory electron transport chain, in this order: nitrate, NO_3^- ; manganese oxide, MnO_2 ; iron hydroxide, $Fe(OH)_3$; sulfate, SO_4^{2-} ; and carbon dioxide, CO_2 . The likelihood that microorganisms will switch from aerobic to anaerobic reactions is indicated by the redox potential of soil. When the redox potential is >400 mV, O_2 is the main electron acceptor. From 200 to 400 mV, the weakly reducing conditions favor O_2 , NO_3^- and MnO_2 as electron acceptors. However, a redox potential of 200 to -100 mV is moderately reducing ($Fe(OH)_3$ as the electron acceptor) and <-100 mV is strongly reducing (SO_4^{2-} and CO_2 are the electron acceptors). Therefore, the O_2 concentration and the redox potential determines the oxidation-reduction status of the rhizosphere.

Nutrient and salt concentrations in the rhizosphere

Water moves from the bulk soil to the rhizosphere, mainly through mass flow in response to differences in matric potential, carrying with it soluble nutrient ions and low molecular weight compounds. These substances are needed for the proper growth of roots and their rhizobiome. However, the rhizobiome also contributes directly to the nutrient supply for plants. This can be by acquiring nutrients from the atmosphere (e.g., biological nitrogen fixation), solubilizing soil minerals to release mineral-associated nutrients (e.g., phosphate-solubilizing bacteria) or mineralizing soil organic matter to recycle organically bound nutrients.

One way that roots create gradients to increase nutrient availability is through the positive priming effect, which transfers carbon-rich root exudates into the rhizosphere (Fig. 4). In sunflower (*Helianthus annuus*) and soybean (*Glycine max*) crops, the root system had 27–245% more soil C mineralization, and 36–62% greater N mineralization than the bulk soil (Zhu et al., 2014). Living roots increased the microbial biomass carbon by up to 28% and stimulated the activity of cellulose-degrading and lignin-oxidizing enzymes. The extent to which the enzyme activity is stimulated by roots depends upon the microorganisms involved, as well as crop and soil properties. For instance, the enzymes that degrade organic carbon and organic nitrogen substrates were elevated within 1 mm of the root, whereas phosphate-hydrolyzing enzymes increased up to 3.5 mm from the root of lentil (*Lens culinaris*) and maize (Razavi et al., 2016), relative to the bulk soil. Phosphorus cycle. This suggests greater activity of carbon-degrading and nitrogen-mineralizing microorganisms near the root surface, whereas phosphorus mineralization may be associated with endophytic fungi, whose hyphae extend a greater distance from the root surface. Phosphorus mineralization could be the result of phosphatase enzymes secreted by the fungi but may also be from phosphatase-producing bacteria that swim along the fungal hyphae to microsites with abundant organic phosphorus. This underscores that physical, chemical, and biochemical factors influence root-rhizobiome interactions, illustrating the need to fully describe the environmental context and to look beyond biological explanations for observed phenomenon.

Soil salinity is a growing global problem because of the naturally high salt concentration in many arid and semi-arid soils, and in irrigation water. As the salt concentration increases in the rhizosphere, this lowers the osmotic potential and prevents root cells from absorbing water. Roots that absorb Na^+ and Cl^- from the soil water become imbalanced in their osmotic and redox potentials, leading to a reduced photosynthesis rate and to oxidative stress in cells. Furthermore, a high concentration of Na^+ in the rhizosphere can induce Ca^{2+} and K^+ deficiencies in the plant, due to competitive inhibition in the uptake of these essential nutrients resulting from the ionic imbalance of the soil water. However, plants have a natural tolerance for salts that is enhanced by the presence of naturally occurring bacteria and fungi in the rhizosphere (Table 3; (Abbas et al., 2019)). The rhizobiome can directly stimulate

Fig. 4 Biological interactions that increase the rate of soil organic matter (SOM) mineralization and nutrient biogeochemical cycling in the rhizosphere and the mycorrhizosphere (i.e., through bacteria and fungal iterations). EPS: extracellular polymeric substances.

Table 3 Salt tolerance in crops is enhanced by root-associated bacteria that support plant growth through a variety of mechanisms.

Crop	Root-associated bacteria	Mechanism for salt tolerance
Tomato (<i>Lycopersicon esculentum</i>)	<i>Achromobacter</i> sp. <i>Streptomyces</i> sp.	Reduce ethylene level Produce proline
Cucumber (<i>Cucumis sativus</i>)	<i>Acinetobacter</i> sp. <i>Burkholderia</i> sp.	Reduce ethylene content More water uptake and chlorophyll
Wheat (<i>Triticum aestivum</i>)	<i>Aeromonas</i> sp. <i>Serratia</i> sp. <i>Enterobacter</i> sp. <i>Klebsiella</i> sp. <i>Microbacterium</i> sp.	Produce extrapolymeric substances Reduce ethylene production Increase K ⁺ content, produce proline
Barley (<i>Hordeum vulgare</i>)	<i>Curtobacterium</i> sp. <i>Hartmannbacter</i> sp.	Produce proline Produce extrapolymeric substances
Rice (<i>Oryza sativa</i>)	<i>Micrococcus</i> sp.	Production of IAA and siderophores
Maize (<i>Zea mays</i>)	<i>Azotobacter</i> sp. <i>Geobacillus</i> sp.	Improved nutrition Produce proline, more photosynthesis
Wild mint (<i>Mentha arvensis</i>)	<i>Exiguobacterium</i> sp.	Produce extrapolymeric substances
Strawberry (<i>Fragaria ananassa</i>)	<i>Kocuria</i> sp.	Improve phosphate nutrition
Sunflower (<i>Helianthus annuus</i>)	<i>Azospirillum</i> sp.	Greater chlorophyll content
Pea (<i>Pisum sativum</i>)	<i>Arthrobacter</i> sp. <i>Variovorax</i> sp.	Increase nutrient uptake Produce ACC deaminase
Soybean (<i>Glycine max</i>)	<i>Bacillus</i> sp. <i>Pseudomonas</i> sp.	More ACC deaminase activity More proline and IAA
Peanut (<i>Arachis hypogaea</i>)	<i>Brachybacterium</i> sp. <i>Brevibacterium</i> sp. <i>Haererohalobacter</i> sp. <i>Ochrobactrum</i> sp.	Increase K ⁺ content Produce IAA and ACC deaminase
Mung bean (<i>Vigna radiata</i>)	<i>Enterococcus</i> sp. <i>Pantoea</i> sp.	Lower Na ⁺ uptake Greater ACC deaminase
Lentil (<i>Lens esculenta</i>)	<i>Oceanobacillus</i> sp.	Produce extrapolymeric substances

ACC: 1-Aminocyclopropane-1-carboxylic acid; IAA: Indole-3-acetic acid.

Adapted from Abbas R, Rasul S, Aslam K, Baber M, Shahid M, Mubeen F, and Naqqash T (2019) Halotolerant PGPR: A hope for cultivation of saline soils. *Science* 31: 1195–1201. doi: 10.1016/j.jksus.2019.02.019.

plants to extend their root architecture. Microorganisms secrete phytohormones like gibberellins and indole acetic acid that make plant roots grow longer, with greater root surface area and more root tips. Consequently, the roots will gain access to water and nutrients from the soil profile, beyond an area of soil salinity.

Conclusions

Roots attract and associate with a diverse community of bacteria, fungi and archaea that form their rhizobiome. Biological interactions among the root-rhizobiome are controlled by a cell-to-cell communication through the exchange of chemical signal molecules. Advances in phytochemistry and plant metabolomics have made it possible to quantify the hundreds of compounds that are produced and received by roots, as well as the root-associated and endophytic microorganisms in the rhizobiome. We anticipate more discoveries about how these infochemicals control plant responses at the cellular, physiological and anatomical levels. Future investigations will be enhanced by using metagenomic, transcriptomic and proteomic analyzes to understand the genetic basis for the two-way transmission of information between the root and its rhizobiome. This research should provide clues about characteristics of the compatible plant and microbial genotypes. It will also provide insight about the role of non-culturable microorganisms, including archaea, that are generally under-represented in the literature. One outcome from this research could be to identify suitable microbial consortia with potential to enhance plant growth. However, we must remain alert to the environmental factors that induce phenotypic variation in plants and microorganisms. As much of the evidence for beneficial root-rhizobiome interactions comes from well-controlled growth bench and laboratory studies, we recommend confirmatory field studies. This will corroborate the pathways for assembly of diverse rhizobiomes that support resilient crops in sustainable food and fiber production systems.

Abstract

Soil respiration is a useful indicator of global carbon balance and terrestrial carbon exchange with the atmosphere. Different soil carbon pools metabolize at variable rates based on environmental constraints on microbiological activity. Respiration is thus primarily controlled by climatic effects (temperature and hydrology) and soil management. Soil respiration can be measured both on site and in laboratory, with each method possessing distinct advantages and disadvantages relating to actual or potential respiration rates. These tests help us understand the importance of soil respiration as an indicator of soil conditions and C cycling and enable some predictions of changes in soil carbon under climate change.

Key points

- Soil respiration is controlled by complex interactions between climate (temperature and hydrology), land management, and soil microbiology.
- Soil carbon can be divided into pools that respire at different rates depending on their accessibility to microbes.
- Soil respiration can be measured via in-field and in laboratory methods, each of which have advantages in describing the complete picture of soil respiration.
- Soil respiration is a useful soil health and global carbon cycling indicator that is of particular interest under conditions of expanding human society and climate change.

Introduction: Soil respiration as indicator of biological activity

Soil respiration integrates the metabolic processes of all types of organisms living in soil, (including the roots of plants) as they break down organic molecules (i.e., carbonaceous compounds), to harvest the energy necessary for their metabolism. The obtained energy is stored in form of ATP or other compounds capable of transferring electrons to release energy that is employed in downstream metabolic processes. The two main products of respiration are water and gaseous carbon dioxide (CO₂), which can be measured as it leaves the soil. As energy is required for any cellular biochemical processes, respiration is the gatekeeping process regulating metabolic energy fluxes in the cell and can be employed to understand the functional state of a soil. This is why measurements of soil respiration are utilized as best direct indicators of soil activity and health.

As with any biochemical process, temperature and water availability (Fig. 1) are key controlling parameters, and respiration in most soil types is largely an aerobic process governed by the availability of oxygen. Other than in bogs and marshes, in-situ respiration measurements are commonly assumed to reflect aerobic respiration; ex-situ measurement methods actively create aerobic conditions. Furthermore, respiration depends on the availability of carbonaceous molecules and on the availability of all macro- (N, P, K) and microelements (Ca, Mg, Mn...) that are necessary for high-functioning of biochemical processes involved in metabolism of an organism. These elements may be provided during the decomposition of plant or microbially derived organic material or can be made available in ionic or mineral forms through natural biogeochemical processes or as a result of their addition to soils in form of various fertilizers.

Therefore, soil respiration is a proximate indicator tightly linked to many individual processes, primarily respiration of autotrophic organisms, such as plants and algae, the breakdown of carbonaceous compounds by heterotrophic organisms, including bacteria or fungi, and predation. Respiration reflects the stability of the soil food web, which governs the pathways and speed of the transformation of carbonaceous matter along its trophic nodes, and also reflects the impact of management on altering the proportions and types of organic matter, minerals and altering soil heat and water fluxes.

Though total soil respiration is not specific to particular groups or types of organisms (e.g., bacteria or fungi), it nonetheless is a very useful measure of soil condition, as it indicates overall biological activity driven by the presence of carbonaceous substrates in soil and roots, as affected by any external constraints. The term “soil respiration” addressed in this chapter differs from the term “CO₂ emission from the soil surface,” which presumes additional consideration of physico-chemical processes of gas transport in soil profile, while our topic (soil respiration) is more intricately linked with biological nature of CO₂ production in soil.

Fig. 1 Soil respiration response to changes in soil moisture and temperature. (A) empirical function for mineral soil combining an Arrhenius type temperature response - $r = r_{ref} \cdot \exp\left(-\frac{E_a}{R} \left(\frac{1}{T} - \frac{1}{T_{ref}}\right)\right)$ and moisture scaling function based on relative water saturation $f(\theta_s) = a\theta_s - b\theta_s^2$ (Eqs. 20 and 21, respectively, in Moyano et al., 2018); (B) empirical function reflecting soil surface CO₂ efflux (root and soil respiration) optimized for the set of forest and shrubland sites in Europe and USA - $f(T_{soil}, RSWC) = \exp\left(E_0(RSWC) \cdot \left(\frac{1}{T_{ref} - T_0} - \frac{1}{T_{soil} - T_0}\right)\right)$, where $E_0(RSWC) = a_{E_0} + b_{E_0} \cdot RSWC$ and RSWC is relative soil water content (Eqs. 2–5 in Reichstein et al., 2003).

Respiration and global GHG balance

Soil respiration, together with CO₂ assimilation by plants, is routinely estimated as global primary productivity (GPP) and is the driving force behind global carbon cycling between terrestrial and atmospheric pools of carbon. Just as GPP draws down 123.4 PgC of carbon annually and fixes it in various organic carbon forms within the terrestrial ecosystem, so respiration allows for the conversion of C from organic forms back into inorganic CO₂ and its return to the atmosphere (121.6 PgC year⁻¹). Without human usage of fossil fuels, these two forces are in near equilibrium, with a minor increase in terrestrial carbon of +1.8 PgC year⁻¹. The increase in land sink was 3.4 ± 0.9 PgC year⁻¹ during 2010–2019, while CO₂ emission increased by 1.6 PgC year⁻¹ during the same period (Friedlingstein et al., 2020). Thus, while soil respiration is a major contributor to carbon cycling, it is a natural process that counterbalances GPP and ensures global C cycling. However, human activity, such as land clearance, disturbance, and above all, the utilization of fossil fuels contributes additional carbon emissions to this cycle and causes an imbalance, creating a net gain to the atmosphere of 4 PgC year⁻¹, driving climate change.

Aerobic vs. anaerobic respiration in soils

Aerobic respiration is the primary source of CO₂ within soil, as oxygen is critical for determining the rate of soil respiration as it is required for basic metabolism. Water content controls the availability of oxygen via diffusion, and thus determines whether conditions are aerobic or anaerobic. In the absence of oxygen (anaerobiosis), anaerobic respiration employs molecules other than oxygen as electron acceptors, and thus can occur when soils are waterlogged. Anaerobic respiration is energetically less efficient and thus not preferred, and releases a variety of compounds, particularly CO₂, CH₄, and NO_x. Thus, the contribution of anaerobic respiration to the C efflux from soil is much smaller than the main source of CO₂ in soil, which is related to the oxidation of organic substances with O₂. Therefore, CO₂ released from a soil reflects both aerobic and anaerobic respiration. Even if a soil is overwhelmingly aerobic, there will always be anaerobic microsites present within the soil microaggregates, where many small pores are filled with water, causing slower diffusion of oxygen and often high microbial activity, resulting in very small oxygen concentrations. However, these sites account for very small percentages of carbon processing (background levels) and are often ignored in respiration measurements (Smith et al., 2003). In a well-drained soil, anaerobiosis will only continue in soil micropores, but water remains the primary controller on carbon cycling in bogs, which have proportionally more carbon due to functional stasis of plant material in various stages of decomposition due to anaerobiosis.

Plant roots often create specific conditions in the ‘rhizosphere’ by pumping carbonaceous and other compounds into the soil matrix so as to preferentially select for particular microbial consortia, raise the pH, and otherwise create ideal conditions for plant growth. Roots also, however, respire, increasing the concentration of CO₂ and reducing that of oxygen.

Drivers and controls of soil respiration

Soil temperature

Generally, rising soil temperature increases soil respiration (see e.g., Fig. 2), while temperatures near or below zero Celsius suppress respiration. The sensitivity of soil respiration to increases in temperature can be expressed as the Q₁₀ value; that is, the factor by which soil respiration increases for each 10 °C increase in temperature. However, temperature sensitivity of soil respiration (Q₁₀) is also affected by changes in the availability of soil organic carbon, nutrients, and in the soil water potential. Hence, when hydrology is factored in, a substantial amount of Q₁₀ values, especially in areas that are considered very susceptible to climate change (e.g., boreal forests, wetlands) are perhaps less at risk than previously thought, while tropical systems appear to be mostly unaffected by hydrology (Fig. 2).

As enzymes carrying out metabolic activities become inactive at lower temperatures, their activation rates, that is the amount of energy (expressed in kJ mol⁻¹) required to trigger the biochemical reaction carried out by an enzyme, decreases with an increase in temperature. However, the enzymatic apparatus of microbial communities that have acclimated to different temperatures are also particularly adapted to the respective temperature regimes. Cold adapted organisms and cold soil microbiomes are more sensitive to changes in temperature, having lower activation temperatures. At the upper end (greater than 30 °C) microbes slow down or stop, and it is agreed that respiration declines vertiginously for temperatures over 40 °C.

The relationship between temperature and soil respiration might be fitted using an exponential equation:

$$R_T = a \times \exp^{b \times T}$$

Q₁₀, namely when the values are calculated relative to a 10 °C change, may be calculated as:

$$Q_{10} = \exp^{10 \times b}$$

The terms a and b are empirically fitted and vary as a function of water and carbon availability and differ according to the level of adaptation of the soil community to the local climate (i.e., cold vs. hot biomes).

Fig. 2 While Q_{10} is linked to temperature it might be more dependent on hydrology than is usually thought. When hydrology is factored in, high Q_{10} may be lowered such as for boreal forest (compared to tropical savannah or grassland where both are the same); x-axis is temperature-only Q_{10} , while y-axis is hydrologically-sensitive Q_{10} (i.e. reflecting hydrological effects on temp dependency of C degradation). Graph is created using data from Fan et al. (2022). Images copyrighted to the chapter's authors.

Soil moisture

As biochemical processes require water, its availability is a colimiting factor. It is common to describe soil water content in terms of volumetric units, but this does not truly describe its availability. The upper limit of soil available water content, a parameter dependent on its capacity to retain water against gravitational pull, and which varies with the soil texture, is achieved at the field capacity for water, commonly taken to be -33 kPa (-6 to -33 kPa, soil texture and aggregation dependent) matric potential. The lower limit of water availability to plants is the permanent wilting point (PWP) at a matric potential of -1500 kPa; this indicates that only water in pores >0.2 μm diameter is available to plants. At PWP fine textured soils may have as much as 33% water content volumetrically, while sandy soils might have $<10\%$. In direct contact, microbes might be able to access some of this water. However, the water content also affects the diffusion rates of soluble nutrients required by soil microbiota. Drier soils will interfere with the consistent solubilization and diffusion of necessary nutrients (Moyano et al., 2018). In mineral soils diffusion of nutrients ceases at a matric potential of $-14,000$ kPa. In plant litter the nutrients might be available for matric potentials as low as $-36,000$ kPa. as microbes are in immediate proximity of rich organic materials, but below this, desiccation stops microbial activity; these thresholds are uniform across biomes (Manzoni et al., 2012).

It is generally considered that water contents at matric potentials equivalent to field capacity or above (i.e., closer to saturation, matric potential 0 kPa) is available with little restriction. Excessive water, however, will lead to anaerobiosis, that is lack of oxygen, which will halt aerobic respiration. As a rule of the thumb, soil moisture levels of $\sim 50\%$ water-filled pore space are considered ideal for allowing maximal respiration rate without oxygen starvation that results in anaerobiosis (Franzluebbers, 1999). Thus, soil moisture and temperature are closely and intimately linked (Fig. 1): a hot soil without water may have minimal respiration, while a cool soil with ideal moisture may have higher rates.

Another mechanism affecting availability of water to respiring microbes is excess salts in the soil solution. This reduces availability of water to microbial cells through osmotic stress. High ionic strength of the solution can inhibit microbial growth independent of the type of ions. However, ion specific toxicities can affect soil microbial respiration, which is less inhibited by salts containing SO_4^{2-} than Cl^- (Rath et al., 2016). The drying of soil also increases the ionic strength of the soil solution. Fungi are more resilient to increases in the ionic strength of soil solution.

Available soil carbon

As most soil microbes are heterotrophic, soil microbial respiration depends on the availability and accessibility of carbon-based substrate. Soluble and exposed carbon compounds are the immediate source of carbon for soil microbes. Exposed, complex carbon compounds (e.g., cellulose, hemicellulose, chitin, lignin, proteins) need to be degraded before uptake and thus microbes produce

the necessary enzymes. The less available a carbon compound the more the energy expenditure of microbes and thus the less efficient the catabolism. Less efficient organic carbon catabolism results in more respiration per biomass unit. A simple means to describe the efficiency of carbon utilization by a soil microbial community is the CO_2 quotient ($q\text{CO}_2$), which describes the amount of CO_2 respired by a unit of microbial biomass carbon ($\text{unit CO}_2\text{-C unit}^{-1} \text{C}_{\text{mic}} \text{h}^{-1}$). Sugars are an efficient source of carbon that can be immediately employed as energy sources, and thus lead to immediate increases in respiration rates. Bacteria can also take up amino acids that can be directly employed in cell anabolic and catabolic processes, and thus are particularly energy-efficient sources of carbon. Complex organic substances (celluloses, chitin, lignin), which are less available to microorganisms can be degraded more efficiently by fungi, some species of which possessing of specific enzyme systems; this longer degradation and utilization pathway leads to a slower utilization, and thus an apparent lower respiration rate. If carbon sources are easily available, soil microbes deal with environmental stresses through an acceleration of carbon utilization and thus accelerated metabolism, leading to more C to be respired as CO_2 .

Soil carbon pools

Soil organic carbon (SOC) can be conceptually assigned to labile, intermediate and stable carbon pools. The proportion of labile carbon is the main driver of soil respiration, modulated by temperature and moisture conditions. In practice this partitioning is less clearly defined as the definition of each pool is dependent on variably imprecise methods of measurement.

As organic materials enter the soil it is physically shredded and chemically degraded by digestion in the alimentary canal of mesofauna, and through exoenzymes produced by microfauna. Depending on the propensity of a certain type of organic matter to be degraded soil organic matter pools of variable stability form. This leads to a series of particulate organic matter (POM) pools from coarse (4000–250 μm equivalent diameter) to fine (250–50 μm equivalent diameter). The coarser POM is less accessible to microbes. Exposed fine fraction POM (i.e., not physically protected by strong attachment onto charged mineral particles or enclosed within micropores of soil aggregates and not readily accessible to microbes) is more easily degradable by microbes and has been shown to be correlated to soil microbial respiration (Koutika et al., 2008).

Another approach to describe active carbon is to quantify the permanganate oxidizable carbon (POXC). Although POXC is generally positively related to POM and to the soil microbial biomass carbon (MBC), it is more closely related to POM <250 μm and also to heavier (>1.7 g cm^{-3}) rather than lighter POM (Culman et al., 2012). Thus, POXC may be an easy to measure, proximate indicator of the labile fraction of SOM and thus a good indicator of the respiratory potential of a soil.

Dissolved organic carbon (DOC), a complex mixture of mainly hydrophilic fractions of variable aromaticity, is assumed to be easily available to microorganisms and thus a potential driver of respiration. DOC is produced under both anaerobic and aerobic conditions; however, under aerobic conditions the DOC is also rapidly consumed and thus measuring DOC production is less accurate.

SOC that is physically separated from microbial biomass such as physically protected SOC in aggregates, or SOC in the subsurface layers of acid soils, does not participate in microbial metabolism, but it may be made available when soil aggregates are broken apart through soil management such as tillage.

Nutrient availability

As cell metabolism requires nutrients other than C, their availability will affect the interaction between soil microorganisms and soil C pools. Nitrogen (N) and phosphorus (P) are the nutrients required in the largest amounts as they are critical to the production of organic molecules essential to the functioning of a cell. N is an essential component of proteins and thus critical to enzymatic activities, whereas P is essential for management of cellular energy (i.e., ATP). Each organism assimilates C and nutrients to proportions necessary for their structural and functional components. Imbalance in C and nutrient provision will affect cell physiology and thus the proportional likelihood for C to be retained in microbial biomass or lost in respiration. The C:N ratio is the most common indicator used in soil management to explain the likelihood for C to be retained by soil heterotrophs (i.e., fixed) or be lost to respiration. The C:N ratio controls the balance between immobilization and mineralization of N. Insufficient N will limit the amount of soil organic C that can be retained by heterotrophs. As fresh litter with a C:N:P ratio of 3000:46:1 is decomposed, the nutrients are concentrated in soil microbial biomass with a ratio of 60:70:1 (Sinsabaugh et al., 2009). The excess C is thus not included in the biomass and can be respired as CO_2 . Nevertheless, given that some complex organic polymers, such as lignin, are not easily decomposed, the average organic matter of soil has a ratio of 186:13:1.

P affects soil heterotrophic respiration in a manner partially similar to N. If available P is added to nutrient rich and stable soil systems it may increase SOC, suggesting it is the limiting factor. Co-addition of N and P may have logically consistent but variable effects depending on the original state of the receiving soil: a minor increase in respiration is likely.

pH

For constant moisture and temperature conditions, microbially driven respiration will decline as soils acidify. Neutral to slightly alkaline pH conditions favor microbial activity and thus the greatest respiration rates permitted by conditions of temperature, moisture and carbon availability. Survival and growth at greater acidity (lower pH) needs additional energy expenditure, meaning that larger fraction of C will be diverted to catabolism and relatively more CO_2 will be respired by soil microorganisms. So, the net effect of soil acidification on cumulative CO_2 production depends on the two opposite trends: decrease of general decomposition activity and increase of respired C fraction due to lower carbon use efficiency at low pH.

Soil organic matter supply and quality

Soil organic matter, as the supplier of carbon to subsurface heterotrophic organisms, is the primary driver of soil respiration, which means that land managers must consider its supply and quality. Carbon supply comes from living organisms, most of which is generated by continuous plant cover (as found in nature), but actions that reduce or eliminate this supply (e.g., residue burning or removal, clearcutting, land clearance) will, over the long-term, starve the soil of its carbon and decrease its respiration, often changing the community of organisms that reside and respire. As described above (see "Available Soil Carbon"), carbon quality matters as well; more complex plant matter will add in a greater variety of carbon, which in turn can support more diverse and larger populations of organisms. Indeed, one of the hallmarks of natural landscapes is that they often accumulate carbon over time, while human land management (agriculture) has historically depleted soil carbon through reducing the quality of plant inputs and the quantity of matter returned to the soil. Adding compost or manure can help alleviate these problems, and soils can be regenerated through the addition of different and complex forms of carbon (thus favoring stable, long-term respiration).

Interplay of temperature and hydrology

For much of the biosphere, respiration increases with increasing temperature, unless it is hydrologically limited. Arid regions, as previously mentioned, have excess heat but limited water, hence respiration is controlled by water access and plant presence (which decreases albedo and increases soil moisture), not by temperature. At the opposite end of the spectrum, boreal regions would seem to be primarily influenced by lack or presence of heat, but there is more complexity than this. In particular, the interplay of temperature and water is what controls respiration. For example, winters with less snowfall cause deeper frost penetration of longer duration and more mechanical degradation of C through cryoturbation, which in turn means there is more C available for metabolism. On the other hand, warmer winters (with shallower freeze-thaw and snowmelt) can cause massive flushes of DOC into local waterways (Haei et al., 2013). Increased rainfall can protect C through saturation of the soil, whereas moderate drying events can result in runaway respiration as C is exposed. In areas such as the southern Siberian forest (e.g., Mongolia), which have a transect with arid and boreal conditions, a slight decrease in moisture or increase in temperature can be enough to cause natural degradation of forests and their replacement by grasslands (Munkhjargal et al., 2020). Finally, podzolic forests in particular have interplays with pH, which, although caused by coniferous vegetation and high rainfall, is not a direct control of respiration but rather a useful predictor of its viability (more acidity often is linked to more recalcitrant litter, and thus lower respiration).

Impact of management on soil respiration

Practically, soil respiration is a near-absolute measure of carbon leaving the soil in a gaseous form, and in this way is closely related to global carbon dynamics: increased respiration means more carbon lost from the terrestrial system to the atmosphere. It also closes the carbon cycle that starts with its photosynthetic fixation by autotrophs. However, the value for the rate of soil respiration is also a highly contextual number that varies depending on the climatic or soil conditions that drive it, even under conditions of 'equal carbon.' One example is arid soils; many of these soils (e.g., Mediterranean, North American desert) are characterized by often high temperatures but rainfall that is sporadic and often confined to a single season or month of the year. Soil microbial populations adapt to these conditions by having a very low steady-state respiration followed by rapid metabolism when rare rain events occur, often hundreds of times larger than when dry. Wetlands are another example: high water table and constant anaerobic conditions predispose them to have reduced respiration, but when drained or during dry spells, the extremely high carbon content of these soils is very susceptible to destructive metabolism. Respiration in agricultural soils often does not match natural soils of the same climate or topography, as the transition from natural carbon-rich systems to highly-managed agricultural systems can render the soils more homogenous in nutrients, carbon, and water content compared to natural systems. Although there are ways to improve carbon retention and input in modern agriculture (e.g., diverse cropping rotations, organic inputs, no-till), the relatively carbon-starved nature of modern farming means that these systems have lower stable reserves and inputs of carbon, less diverse microbial populations, and therefore far smaller respiration rates than natural systems. Additionally, the proportion of C respired versus the total is often higher (more lost) than in natural systems, where higher respiration is outstripped by higher inputs. Natural systems such as forests or grasslands will still have differences between types of natural systems, e.g., grasslands may have lower respiration than forests due to water deficit, despite the low C:N nature of grassland soils that otherwise promotes respiration. Finally, different soil types with similar climatic conditions may have very different respiration: a Podzol adjacent to a Luvisol will often have lower respiration, as the Podzol is more acidic and nutrient starved. Hence, interpretation of respiration information requires a whole-system approach that considers how a given location's unique topographical/climatic/managed state affects its respiration.

Drainage

In natural systems, poor drainage often results in large accumulations of C. Since anaerobic soil conditions reduce growth and yield or kill plants, farmers maximize drainage via tillage, rock removal, leveling land, or introducing artificial drainage schemes. This

often increases respiration, as the soil is better aerated and more frequently tilled. However, at the same time, better plant growth and less anaerobiosis means more C inputs to soil and decreased emission of CH_4 and NO_x .

Tillage

Inversion and intensive tillage act to break up compaction, mix and homogenize the soil, and aerate it, all of which increase respiration in the short term by providing maximum oxygenation to the soil. However, in the long term, in addition to accelerating respiration, tillage can also retard it by causing compaction, anaerobiosis, poor structure, and impaired drainage, but also by burying C and rendering it less accessible to microbial activity (especially via 'deep plowing,' which inverts the uppermost 0.5–1 m of the soil with the subsoil beneath it). No-till is often recommended as a way to retain or increase soil C and seems to be particularly suited to water management in dry regions, but it is by no means a complete solution, for it primarily redistributes C in the profile (concentrating it in the uppermost 5 cm) rather than evenly throughout the plow-layer as under tillage. Hence, while no-till improves soil moisture and biological activity compared to the drier and highly aerobic conditions of tillage, it still does not consistently increase carbon sequestration.

Nutrient management (mineral vs organic)

Choice of fertilizer can affect respiration. Since most soils are N-limited rather than C-limited, mineral fertilizers tend to promote maximum respiration at the expense of soil organic matter and C retention (since plenty of N allows for even recalcitrant C to be metabolized), and further, select for r-strategist bacteria suited to rapid metabolization. Organic fertilizers (e.g., compost, manure) can have similar effects, but since most also contain a significant source of C alongside N rather than pure N, they are more likely to either have only mild effects on soil C, or in the case of some soils, increase it long term, a strategy that has been used for millennia to control soil fertility. Either way, fertilizer application will increase overall soil respiration, and very recent applications can cause artifacts when measuring it.

Cover crops

The use of cover crops can have contrasting effects on respiration that occur simultaneously. Increased or continuous plant cover can reduce respiration by improving aggregation, infiltration, increased diversity of soil biota (earthworm, insect, mite, etc.) resulting in better plant litter incorporation into soil, and functionally stable microbial community (dominating K-strategists). There can also be an increase in soil respiration since superior aggregation and infiltration allow for more ideal conditions for respiration, while the increased C processing, litter diversity, and penetration into the soil matrix can likewise increase available labile C to fuel respiration.

Application of soil respiration measurements in agronomy and ecology

Estimation of soil organic matter decomposition rates and soil C balance

Soil respiration measurements can be used to estimate soil organic matter decomposition rates as well as the overall soil carbon balance. This can be conceptually done through the use of three numbers: maximum soil respiration ($\text{mg CO}_2\text{-C kg}^{-1}$ soil) calculated on a basis of time (e.g., hours or days) and calibrated by temperature and moisture (e.g., water filled porosity), total yearly soil inputs of carbon (via plant biomass, e.g., g C kg^{-1} soil year^{-1}), and the soil organic matter content of the soil (e.g., percentage of SOM which is assumed to have a mixture of C, N, P, cations, etc.). Soil respiration numbers can be used to extrapolate the carbon leaving the soil yearly and this can be compared to plant inputs to determine the state of the soil carbon balance (e.g., $\text{mg CO}_2\text{-C kg}^{-1}$ soil lost per year compared to g C kg^{-1} soil year^{-1} input for a net gain of g C kg^{-1} soil year^{-1}), or to organic matter to determine how much native soil carbon is lost (e.g., 1000 g C kg^{-1} soil year^{-1} respired is about 1.3% of total SOM lost per year). If inputs balance output or exceed respiration, then the soil will have a net gain of carbon.

In practice, potential carbon mineralization rates can be estimated in laboratory incubation experiments, where relative size of theoretical carbon pools and their rate of decomposition can be estimated and results then used for comparative analysis of, for example, soils under different managements.

Index of soil quality and soil health

Soil respiration is an important tool currently utilized as an integral part of soil quality and health indices (e.g., Cornell Comprehensive Assessment of Soil Health, EU Soil Health Law). Since soil respiration measures biological activity constrained by abiotic factors, it is a very important response variable that connects abiotic features and soil management to the reality of soil life. Generally speaking, greater soil respiration values indicate better soil conditions (respiration as proxy for biological activity and C availability), and by referencing the soil to others in different climates and locations, specific land management practices can be assessed for their effect on soil respiration dynamics and thus soil health or quality. However, in some cases a large respiration value may be indicative of unsustainable biological activity (ultimate degradation of soil C). Therefore, interpretation and contextualization of respiration data is vital to make indices a useful tool, both by comparing to other locations of a similar type (e.g., agricultural to agricultural, not forest, within same climatic zone) and by measuring other important soil features of the soil quality or health index (e.g., soil aggregation or labile C).

Measuring respiration

Soil respiration measurements as an integrated proxy for soil biological activity

Soil respiration represents the sum of biological processes in the soil that produce CO₂ and is therefore a gross measure that does not specify the activity of any one organism. Given that plants, as autotrophs, contribute to both respiration and fixation of carbon (GPP), it is helpful to try and partition out different sources of CO₂ flux. Further, the response of autotrophic and heterotrophic respiration to changes in environmental factors (such as solar light intensity, soil moisture, and air and soil temperature) can differ. Therefore, separating CO₂ flux from decomposing soil organic matter in bulk soil from that found in the rhizosphere of living plant roots can help in understanding the mechanisms driving soil respiration. This separation is methodologically difficult however, as direct mechanical methods are required for extraction of root fragments from soil, and the destruction of fine root hairs may cause spikes in respiration that differ from undisturbed roots, and this is also true for respiration in disturbed soil samples without roots (Hanson et al., 2000). Currently no universal method applicable for separation of autotrophic and heterotrophic respiration is available, though a number of different indirect methods are available for researchers. They can be applied in situ with no disturbance, or ex-situ with evaluation of possible bias caused by measurements (Gavrichkova et al., 2019; Kuzyakov, 2006). These methods are detailed in the following sections.

Measuring respiration on site

Soil respiratory flux can be measured in-situ utilizing semi-permanent chambers that are connected to an instrument. A common practice is to place a base frame, usually a ring, into the ground with a chamber temporarily topping the frame to form a seal. This has the advantage of minimal disturbance but can result in root cutting and artificially increase the levels of CO₂ measured. The challenge with in-situ respiration is the extremely large variability; environmental factors, such as sunlight, temperature, moisture, and time of day are not controlled, roots of many different plant species may be present and respiring, and smaller organisms may also contribute actively. It must be stressed, that direct in-situ measurements are labor and time consuming and need to be organized correspondingly to account for temporal and spatial variability. Hence, contextualizing laboratory measurement (e.g., basal respiration) to partition the proportion of respiration caused by microbes versus these other sources, can help understand the full implication of in-situ measurements collected under high variability (Ananyeva et al., 2020). Nevertheless, more accurate, high-end equipment (e.g., laser spectroscopy) is now available for field measurements; with proper data management it can help overcome the weaknesses of traditional methods.

Use of isotopes for partitioning of soil respiration

Carbon dioxide emitted by soil originates from several sources (e.g., root and microbial respiration) and usually these sources have different isotopic-C signatures. The most common method to distinguish the origin of CO₂ is to estimate the ¹³C isotopic abundance of the carbon atom in CO₂. The ¹³C enrichment of organic-C originating from the plants with different types of photosynthesis (C3 and C4) can be easily differentiated, and this is used in so-called natural enrichment difference method, when, for example, soil organic matter is formed in long term from the C3-plant residues, whereas currently growing C4-plants respire CO₂ with isotopic signature remarkably different from the soil-derived CO₂. ¹³C isotopic enrichment can differ for CO₂ produced from different soil horizons, or from different organic compounds in soil organic matter. The historical timeline of soil C accumulation can be followed also using ¹⁴C tracer. ¹⁴C produced by past nuclear tests leaves a distinct trace (radioactivity) in the organic matter formed at that time. Finally, growing plants under an atmosphere of ¹³C-enriched CO₂ in the field or lab conditions can help in disclosing the temporal pattern of root and rhizosphere (rhizomicrobial) respiration and partitioning of soil and root derived carbon. This kind of research necessitates additional costs and efforts (so-called free-air carbon enrichment experiments, see e.g., Hungate et al. (2009)).

Ex-situ measurements of respiration

Laboratory measurements are preferred in respiration work due to their reduction of the inherent variability of nature and the possibility of partitioning out the different sources of respiration in a systemic manner. That said, laboratory measurements do not necessarily reflect in-situ conditions. Ex-situ respiration is often at a constant, controlled temperature and moisture, may involve substantial processing (and thus disturbance) of soil, including sieving, rock and plant detritus removal, and often uses volumes of soil that are miniscule (e.g., sometimes an aliquot of small as 1 g soil) compared to the complete, sometimes multi-meter deep soil profile. All of this creates particular challenges for ex-situ measurements, centered around two questions: how do we avoid introducing sources of bias (e.g., by incubating too small a soil volume that introduces respiration artifacts that are not reflective of field conditions), and how do we factor soil sensitivity to altered conditions from in-situ, especially the disturbance inherent to ex-situ measurement? The following sections summarize some of the ex-situ measurements available.

Basal respiration is a measurement of heterotrophic microbial respiration in coarse-sieved, root-free soil under controlled temperature and moisture conditions (but no drying or other processing of soil). If roots are present, they are separated from soil before analysis, and soil is standardized by coarse sieving (e.g., 4 mm sieve). The soil at optimal moisture for microbial activity (40–60% of water holding capacity) is then investigated under controlled temperature conditions. Basal respiration is a powerful tool, but basic techniques have not changed much in the past 100 years: it focuses on optimizing incubation conditions for all soil microorganisms to maximize response. Nevertheless, the temperature might be larger than the annual means in many soils (i.e., 25 °C). Sieving also has the benefit of eliminating rock fragments and other large particles that cause erratic respiration due

to surface-to-area considerations. However, elimination of variability may also result in respiration readings that are less relevant to field conditions (even if they more carefully partition respiration from other sources), and so basal respiration can overestimate in-situ respiration since soil is disturbed moving to the laboratory, and it gives little indication of the maximum potential respiration of the soil, nor can it partition different microbial community respiration contribution. An alternative approach for basal respiration is to incubate for some time (e.g., 20–30 days) while keeping the soil at a steady moisture through gentle rewetting before measuring the samples (e.g., Comeau et al., 2022). This has the advantage of eliminating the effect of the disturbance but takes a vast amount of time and resources committed to allow for such long-term incubations and is therefore difficult to justify commercially. Although used frequently by research scientists, basal respiration is difficult for commercial operations due to the need of the customer to keep the sampled soil moist (and therefore in climate-controlled conditions) to avoid microbial die-off or anaerobiosis. One option that allows farmers to perform basal in-situ (i.e., sieving a volumetric quantity in-field, placing in an airtight container, and measuring it under controlled temperature conditions) is the Solvita paddle (Haney et al., 2008).

Substrate-induced respiration (SIR) aims to determine the microbial response to the addition of a particular substrate, whereas basal respiration gives a gross estimate of overall microbial activity in soil without its stimulation. For SIR, the response of a consortium of organisms serving a particular biological function (e.g., hemicellulose degraders) is tested by the addition of an appropriate easily-available substrate, necessary for the growth. This substrate is expected to support rapid growth by this consortium if present in the soil, and the resultant respiration indicates potential activity of the microbial population responding to this substrate. After soil sieving and optimization of water content (similar to preparation for basal respiration measurement), the samples are incubated for 24–96 h, during which CO₂ concentration (or production rate) is recorded by corresponding equipment (e.g., GC or IRGA). The greatest benefit of SIR is providing quantification of microbial biomass of microorganisms responding to the specific substrate. After calibration, the determination of initial (4–6 h) SIR after glucose amendment was proposed as standard method for the total soil microbial biomass (Anderson and Domsch, 1978) and since then widely used by soil scientists. Measurements of CO₂ production rate over longer periods (up to 48 h) after soil amendment with carbon and nutrient sources can be used for the estimation of microbial growth kinetics and partitioning of dormant and active fractions of microbial populations (Blagodatsky et al., 2000; Panikov and Sizova, 1996).

Burst Respiration relies on the Birch phenomenon noted with some soils, wherein soil drying followed by wetting induces a ‘burst’ of respiration, presumably as inert microbial populations in hibernation reactivate with the reintroduction of water and rapidly consume available carbon to increase their populations (possibly including microbial biomass alongside other labile C). Burst is performed by drying soil between 35 °C and 75 °C (hotter or cooler introduces too much variability), followed by 2 mm sieving or rolling, and then remoistening an aliquot of soil (e.g., 30 cc) to 50% water filled pore-space conditions (Franzluebbers, 1999). The burst of respiration is measured at uniform temperature, usually 20–25 °C, for maximum microbial response. Burst can be read over 1–72 h, though the respiratory fluxes tend to diminish after 24 h. Burst respiration is a measure of the maximum potential of a soil to respire carbon, and therefore is a good way to measure soil sensitivity to unusual (or regular) climate conditions, such as drought-wet cycles, and can serve as a measure of how much C can be easily metabolized and lost under ideal moisture and temperature conditions (Laffely et al., 2020). Its greatest advantage is that it creates far less variable and highly uniform conditions for soil testing, and it can be performed at any time since the soil is dried immediately. Burst is a useful predictor of the susceptibility of soil C stocks to drying-wetting cycles, and it is well suited to rapid laboratory analysis. Its primary flaw is the yet unclear relationship to actual (in situ) respiration, and whether burst can properly characterize soils that never experience dry-wet cycles.

Respiration and climate change

Climate change has the potential to drastically accelerate soil respiration, but with actual absolute changes being ecosystem and management dependent. Annual net plant primary productivity exceeds respiration and continues to do so along with removing 25% of annual fossil fuel emissions. The remaining 75% of emissions, however, accumulates in the atmosphere and drives global climate change. Furthermore, the ability of natural and human-managed ecosystems to function at peak efficiency has decreased in the past century, with global soil degradation resulting in the loss of ~50–75 Gt of soil C to the atmosphere, and the mechanism by which this occurs is accelerated C respiration, resulting from formerly-protected C being exposed to microorganisms through erosion, overzealous tillage, inadequate plant cover, and other poor land-management techniques. Further, climate change itself can act to accelerate soil respiration, especially when temperature-limited (e.g., boreal regions). However, shifting precipitation patterns may create differing effects; too much or too little water could slow or stop respiration in some regions. Increased CO₂ concentrations and warmer temperatures could also increase plant primary productivity, which could cause a negative feedback loop stabilizing the C cycle. However, the greatest risk is that erratic cycles of temperature and moisture could cause much of the ecosystem to be increasingly exposed to wet-dry cycles, which could increase naturally occurring ‘burst’ respiration events, and thus frequent flushes of maximum respiration from soils.

Summary

Soil respiration is intimately related to the C cycle. It is driven by heterotrophic and autotrophic processes and is responsible for cycling C between the terrestrial and aerial environments. Soil respiration is controlled by complex interactions between temperature, hydrology, land management, and biology. Soil C can be divided into different pools based on their origin and availability to microbes; their lability, or lack thereof, drives soil respiration. Soil respiration is strongly affected by human management, primarily via agriculture, but peripherally through human land clearance from natural states, which often causes inevitable losses of respired C to the atmosphere. It is this relationship with humanity that is of particular interest, and our ability to manage global climate change is very closely tied to the global balance of soil respiration and autotrophic productivity. Soil respiration is measured by a variety of in-situ and ex-situ tests, most of which are complementary, not exclusionary, since no single test accurately measures the entirety of soil respiration pools and paths, and each answers different questions.

Abstract

Anaerobic soils are characteristic of a number of different wetland environments including bogs, fens, swamps, marshes, floodplains, coastal marshes and mangroves, and paddy rice fields. They represent a critical feature of the global landscape because of their unique characteristics and role in regulating global biogeochemical cycles. The productivity and functioning of complex wetland ecosystems is greatly determined by the physical, chemical and biological processes of anaerobic soils. The oxygen-depleted environments that characterize these soils lead to a systematic modification of the microbial community structure and related processes, with important implications on the agronomical, ecological and environmental functions of these soils.

Key points

- Anaerobic soils occupy an important niche in the biosphere, and their importance in wetlands and paddy rice soils is widely recognized. They occur when or where oxygen consumption by soil biota exceeds oxygen supply via diffusion into the soil matrix.
- Saturated soil conditions support microbial populations adapted to anaerobic environments, largely facultative and obligate anaerobic bacteria and archaea.
- Fluctuations in available oxygen and other electron acceptors have significance for regulating biogeochemical cycles of nutrients in anaerobic soils. The redox potential (E_h) of a system may be seen as a characteristic or predictor of the prevailing biogeochemical processes.
- Microbial metabolism including both reduction and oxidation processes directly impacts the forms and fate of nitrogen, iron, manganese, sulfur, and carbon in anaerobic soil systems.
- Wetlands are productive ecosystems and store 20–30% of the global SOC pool (estimated 650 Pg carbon). They are valued for their function as sinks, sources, transformers of nutrients, but are also a significant source of greenhouse gas emissions including both nitrous oxide and methane.

Introduction

Anaerobic soils occur when or where oxygen consumption by soil biota exceeds oxygen supply via diffusion into the soil matrix. This condition is also termed ‘soil anaerobiosis’ and results in a predominantly oxygen-depleted environment in the soil profile. The creation of anaerobic soils is generally linked with water saturation or flooding, though anaerobic conditions may also occur in soils amended with heavy rates of organic materials, animal wastes, biosolids, and composts, as well as soils treated with ammoniacal fertilizers. Once a soil becomes water saturated, the supply of oxygen is immediately reduced due to the displacement of oxygen contained in the available pore space. Following consumption of the relatively small amount of available oxygen in the pore water, oxygen can only be supplied to respiring organisms through the process of diffusion from the nearest aerobic zone. This process is comparatively slow under saturated soil conditions as oxygen diffusion in water is approximately four orders of magnitude slower than through air. Under these conditions, even moderate rates of soil or root respiration can quickly deplete available oxygen and result in anaerobic soil conditions.

Anaerobic soils are characteristic to a number of different wetland environments including bogs, fens, swamps, marshes, floodplains, coastal marshes and mangroves, and paddy rice fields. Wetland soils are widely distributed throughout the world and can be found in all climates, ranging from the tropics to tundra, except for Antarctica. Approximately 6% of the Earth’s land surface, which equals approximately 800 million hectares, is covered by wetlands. They represent a critical feature of the global

landscape because of their unique role in regulating global biogeochemical cycles. In these landscapes, anaerobic conditions are strongly linked to their hydrology and may arise due to inundation (e.g., intertidal zones) or saturation by surface or ground water at a frequency and duration sufficient to strongly limit the diffusion of oxygen into the soil. In any given landscape, wetlands are generally located in areas with a low elevation and high water table.

Anaerobic soils are generally associated with poorly drained, heavy textured soils that retain water during rainy periods or after irrigation events, or with soils that have a superficial water table. However, even in well-drained, seemingly aerobic soils, limited oxygen diffusion into structural units such as peds or aggregates may lead to the establishment of anaerobic microsites that are more ubiquitous than previously assumed and have important implications on element cycling in soils. In upland environments, anaerobic conditions may however be temporary and may not last more than a few days, while in wetland environments, soil anaerobic conditions may last for several months. The functioning of these complex wetland ecosystems is greatly determined by the physical, chemical and biological characteristics of anaerobic soils. Since most of our knowledge on anaerobic soils has been gained through research in wetlands and paddy rice fields, this chapter will largely focus on the morphological and biogeochemical features of these types of soils (Kögel-Knabner et al., 2010).

Physical characteristics

Soil volume primarily comprises solid matter, water, and air, with upland mineral soils generally consisting of about 50% by volume of solids, 25% of water, and 25% of air. Variations in soil moisture contents influence the air-filled pore space of soils, which are extremely important for oxygen diffusion into the soil from the atmosphere. In water-saturated mineral soils, approximately 50% of the soil volume is occupied by solid constituents, while the remaining 50% is occupied by water. In wetland organic soils, a large proportion (up to 80%) of soil volume is occupied by water, with SOM and mineral matter occupying less than 20%. Since gaseous exchange with the atmosphere in upland soils is not restricted because of the connectivity of air spaces, the gaseous composition of soil pores in about 10–21% oxygen, 0.03–1% carbon dioxide and trace amounts of nitrous oxide and ammonia. However, an increase in water-filled pore space limits gaseous exchange with the atmosphere, which is greatly reduced (ca 10,000 times slower) and the gaseous composition of air spaces becomes depleted in oxygen and dominated by reduced chemical forms that are regulated by associated biogeochemical processes (Ponnamperuma, 1972) (Fig. 1). In recently flooded soils, nitrous oxide (N_2O) can be present as a result of denitrification of nitrate nitrogen (NO_3^- -N). In moderately reduced soils, H_2S can be observed, followed by methane (CH_4) under more reducing conditions. In highly reduced soils, ethylene (C_2H_4) and phosphine (PH_3) can even be observed.

Soil structure can also be influenced by water saturation. For example, rapid water saturation can physically break down aggregates due to slaking when air inside aggregates is compressed or swelling occurs in the presence of expandable 2:1 clay minerals. Similarly, anaerobic soil conditions may also enhance particle dispersion and aggregate breakdown via chemical mechanisms, such as reduction of structural Fe, the reductive dissolution of Fe (hydr)oxide coatings, or an increase in soil pH that may enhance surface charge and repulsive forces between soil particles. Moreover, reducing conditions may promote the dissolution of organic matter and Fe (hydr)oxides that serve as strong aggregate binding agents.

Biological characteristics

Saturated soil conditions support microbial populations adapted to anaerobic environments (Liesack et al., 2000). After the soil becomes saturated, most of the aerobic organisms become quiescent or die, and new groups, largely facultative (organisms which can function under both aerobic and anaerobic environments) and obligate anaerobic bacteria and archaea, take over. Aerobic microbial populations are then restricted to zones where O₂ is available. Fungi, which are active in upland environment, are also a significant component of the decomposer community in wetlands (e.g., surface soils), but are generally inhibited, primarily due to

Fig. 1 Various inorganic oxidized and reduced compounds in upland and wetland soils.

absence of O_2 and alteration in soil pH (acid to neutral) under anaerobic conditions. Despite this inhibition, select fungi remain active under low oxygen levels and have an important role in anaerobic processes such as fermentation.

At the soil–floodwater interface, saturated soils can support the growth of microphytic communities, including a variety of planktonic, epiphytic, and benthic algae and fungi. Many of the species in these microbial assemblages have the capacity to carry out photosynthesis. Diel fluctuations in dissolved O_2 produced as a consequence of photosynthesis often increase the O_2 levels in the floodwater beyond saturation levels during daytime which then decline to low levels during night-time. These large fluctuations in available oxygen have special significance in wetlands for regulating biogeochemical cycles of nutrients.

Wetland or anaerobic soil conditions also support the presence of hydrophytic vegetation, or plants that are adapted to the reducing wetland environment. These plants include almost 2000 species that are only found under wetland or flooded soil conditions. Hydrophytic plants have unique characteristics to adapt to oxygen-deficient conditions, including physiological adaptations (such as capability to respire anaerobically), anatomical adaptations (such as development of intercellular air spaces), and morphological adaptations (such as water roots and adventitious roots). Some plants can facilitate (passively or actively) O_2 transport into their roots, some of which may leak out creating aerobic rhizosphere zones in the soil. With these adaptations, hydrophytic plants are able to survive under reducing conditions considered toxic to other macrophytes. In many cases, adapted plant communities become the dominant source of organic matter in wetland systems.

The presence of aerobic and anaerobic zones affects the composition and distribution of organisms in flooded soils, with different compartments (e.g. the oxic surface soil, the rhizosphere, the anoxic bulk soil) being characterized by different physiochemical conditions leading to microscale chemical gradients that control the activity and distribution of functional groups of organisms. These zones consist of metabolically related organisms, e.g. oxygen-respiring bacteria and archaea, nitrate reducers, iron reducers, sulfate reducers, as well as fermenting bacteria and fungi, and methanogenic archaea. The concerted action of all functional groups of microorganisms drive element cycling in anaerobic soils.

Besides the spatial distribution there is also a temporal development of organism groups driven by the transition of soil conditions from aerobic to anaerobic metabolism. The shift from aerobic to anaerobic respiration causes an overall decrease in microbial biomass and activity under saturated soils conditions, and the rates of many microbially-mediated reactions (e.g., respiration) decline, and some reactions may be eliminated and replaced by new ones. Dynamic environmental conditions are also known to yield microbial communities with high functional diversity and species richness because they host periodically variant conditions for various metabolisms.

Chemical characteristics

When O_2 availability becomes limited, microorganisms must utilize other compounds as electron acceptors to maintain their metabolism. These compounds, many of which are nutrient elements, can exist in both dissolved and solid phases, and include oxidized forms of elements such as N, Fe, Mn and S. As they are utilized during respiration, these elements gain electrons and thus become chemically reduced. The result of microbial metabolism therefore is the conversion of oxidized elements to the corresponding reduced form under anaerobic conditions. When wetland soils are drained, many of the reduced compounds are re-oxidized either by chemical or biochemical reactions. Therefore, in upland or drained soils, oxidized forms of chemical species dominate, while reduced forms dominate in wet soil systems (Fig. 1).

Reduction–oxidation, or redox potential (E_h), reflects the free energy available for reduction (intensity of reduction) or a measure of electron (e^-) activity (Reddy et al., 2022; Zhang and Furman, 2021). The E_h of a system may be seen as a characteristic or predictor of the prevailing biogeochemical processes. Depending on soil characteristics, E_h generally decreases with time and approaches a steady value after flooding. Redox potential is the most common parameter used to measure degree of soil water saturation or intensity of soil anaerobic conditions. The range of E_h values typically observed in soils is from +700 to –300 mV (Fig. 2). Negative values represent high electron activity and intense anaerobic conditions typical of permanently waterlogged soils, whereas positive values represent low electron activity and aerobic to moderately anaerobic conditions typical of wetlands in transition zone. Soils with $E_h > 300$ mV are considered aerobic or upland, where oxygen is used as the dominant electron acceptor. Soils with $E_h < 300$ mV are considered anaerobic or wetland.

Fig. 2 Schematic showing relationship between oxidation–reduction potential and oxidized and reduced conditions in wetland and flooded soils.

Fig. 3 Diagram of aerobic and anaerobic zones and processes of spatial coupling of reduction and oxidation affecting movement of elements in anaerobic soils.

The chemical nature of the reduction process also affects soil pH, electrical conductivity, cation exchange capacity, and sorption and desorption processes. In general, the decrease in soil redox potential under saturated soil conditions is accompanied by an increase in electrical conductivity and ionic strength. The pH of most soils tends to approach neutrality under flooded conditions, with acid soils increasing and alkaline soils decreasing in pH. The increase in pH of acidic soils depends on the activities of oxidants (such as NO_3^- , Fe^{3+} , Mn^{4+} , and SO_4^{2-}) and proton consumption released during reduction of these oxidants under flooded conditions. In alkaline soils, pH is controlled (and generally lowered) by the accumulation of dissolved CO_2 and organic acids.

Accumulation of reduced compounds in anaerobic soils results in the establishment of sharp concentration gradients across aerobic–anaerobic interfaces (e.g. in the rooting zone). The concentration of reduced compounds is usually higher in the anaerobic zones, which results in diffusion toward aerobic areas where they are oxidized (Fig. 3). Similarly, some of the dissolved, oxidized compounds diffuse toward anaerobic areas where they will be reduced. The exchange rates between aerobic and anaerobic zones will determine whether the wetlands soils or sediments are functioning as a sink or source for nutrients. The rate of exchange of dissolved species depends upon: (1) concentration gradient of dissolved species in soil pore water between zones; (2) soil type and other related physicochemical properties (porosity, pH, cation exchange capacity, SOM content); and (3) kinetics of related redox-driven biogeochemical processes that remove or add species to the soil solution.

Biogeochemical processes

The biogeochemical cycling of elements in anaerobic soils are generally very complex and highly dynamic as they (1) depend on the establishment of concentration gradients of oxidized or reduced forms across aerobic–anaerobic interfaces, (2) are influenced by mobilization processes linked to diffusion or mass flow of dissolved species across these gradients or with the predominant water fluxes, as well as losses of gaseous species to the atmosphere, (3) often involve various redox-driven interactions through both abiotic, e.g. adsorption, (co)precipitation, and biotic (i.e. microbial respiration) processes (Fig. 3) (Kirk, 2004; Reddy et al., 2022).

Microbial communities in anaerobic soils play a key role in regulating a number of essential biogeochemical cycles such as carbon, nitrogen, phosphorus, sulfur and metals. Organic matter released by primary producers is degraded by microorganisms to supply carbon, energy and nutrients for growth. Enzymatic hydrolysis of SOM produces various monomers, including glucose, xylose, fatty acids, and amino acids. These simple reduced compounds then serve as substrates for microbial metabolism as chemical energy is released during their oxidation. Bioavailable organic matter therefore contributes to the reduction capacity of a soil as an electron reservoir, however this is also largely modulated by the chemical composition of the SOM available. If present, oxygen provides an electron acceptor (oxidant) for supporting microbial oxidation of reduced carbon compounds (respiration). Thermodynamically, oxygen is the most preferred electron acceptor by microorganisms (Table 1), and as a result, aerobic microorganisms maintain a competitive advantage while oxygen is present. Oxygen is used preferentially because it receives electrons from the reductant material (organic matter) more readily than do other oxidants. The greater energy yield during the aerobic process is due to: (1) complete oxidation of carbon atoms in the organic substrates to CO_2 , and (2) the oxygen redox couple having a relatively high, positive reduction potential. This leads to a large net difference in electrical potentials between electron donor (organic substrate) and terminal electron acceptor (oxygen).

Table 1 Microbial groups involved in various redox reactions in wetland soils.

Redox potential (mV)	Electron acceptor	Decomposition end products	Microbial groups
Aerobic (>300 mV)	O ₂	CO ₂ , H ₂ O	Aerobic fungi and bacteria
Fermenting (less than -100 to +300 mV)	Organics	Organic acids, CO ₂ , H ₂ , alcohols, amino acids	Fermenting bacteria and fungi
Facultative anaerobic (+100 to +300 mV)	NO ₃ ⁻	N ₂ O, N ₂ , CO ₂ , H ₂ O	Denitrifiers
	Mn ⁴⁺	Mn ²⁺ , CO ₂ , H ₂ O	Mn(IV) reducers
	Fe ³⁺	Fe ²⁺ , CO ₂ , H ₂ O	Fe(III) reducers
Obligate anaerobic (less than -100 mV)	SO ₄ ²⁻	HS ⁻ , CO ₂ , H ₂ O	Sulfate reducers
	CO ₂ and acetate	CH ₄ , CO ₂ , H ₂ O	Methanogens
	Organic acids	Acetate, CO ₂ , H ₂	H ₂ -producing bacteria

**Fig. 4** Pathways involved in organic matter decomposition in anaerobic wetland soils. Adapted from Reddy RK, DeLaune RD, and Inglett PW (2022) Biogeochemistry of Wetlands: Science and Applications. 2nd edn. Boca Raton, FL, USA: CRC Press.

Once oxygen is depleted in the soil, bacteria must respire anaerobically. Anaerobic decomposition of organic matter is more complex and less energetically favorable than aerobic decomposition. It is mediated by a complex group of physiologically different microorganisms which participate in the decomposition pathways (Fig. 4). Often, the end product of one metabolic pathway is substrate for the next until the decomposition is complete. Initially, fermenting bacteria mediate the extracellular hydrolysis of high-molecular-weight polymers (i.e., proteins, polysaccharides, lipids, and nucleic acids) and transform their respective monomers (e.g., amino acids, sugars, fatty acids, and nucleotides) to CO₂, H₂, acetate, propionate, butyrate, and other fatty acids and alcohols.

In the absence of oxygen, the microbial use of alternative electron acceptors proceeds in a sequential manner dependent on their electron affinity, energy yield, and related enzyme systems in the bacteria. In this manner, the thermodynamic order of electron acceptor use is NO₃⁻, Mn⁴⁺, Fe³⁺, SO₄²⁻ and finally CO₂ (Table 2). Anaerobic respiration is typically reflected in temporal variations in the concentration of reduced/oxidized species of the different redox couples involved, as the most favorable electron acceptors are utilized first (Fig. 5). However, the exclusion of less-favorable respiration pathways is not complete, resulting in considerable overlap between the different forms of organic matter mineralization. The rate at which electron acceptors are consumed in soil systems depends on their concentration, the availability of organic compounds, and the activity of the microbial population involved in the reductive processes.

Nitrate reduction can occur under hypoxic to anoxic conditions through two major pathways: (1) Denitrification, the progressive microbial reduction of nitrate or nitrite to N oxides and molecular N₂ (NO₃⁻ → NO₂⁻ → NO → N₂O → N₂); (2) Dissimilatory

Table 2 Summary reactions for microbial respiration pathways in anaerobic soils.

Electron acceptor	Reaction coupled to glucose oxidation	ΔG° (kJ mol ⁻¹)
O ₂	C ₆ H ₁₂ O ₆ + 6O ₂ → 6CO ₂ + 6H ₂ O	-2879
NO ₃ ⁻	5C ₆ H ₁₂ O ₆ + 24NO ₃ ⁻ + 24H ⁺ → 30CO ₂ + 12 N ₂ + 42H ₂ O	-2713
MnO ₂	C ₆ H ₁₂ O ₆ + 12MnO ₂ + 24H ⁺ → 6CO ₂ + 12Mn ²⁺ + 18H ₂ O	-1916
Fe(OH) ₃	C ₆ H ₁₂ O ₆ + 24Fe(OH) ₃ + 48H ⁺ → 6CO ₂ + 24Fe ²⁺ + 66H ₂ O	-418
SO ₄ ²⁻	C ₆ H ₁₂ O ₆ + 4H ₂ O → 2CH ₃ COO ⁻ + 2HCO ₃ ⁻ + 4H ₂ + 4H ⁺	-207
	CH ₃ COO ⁻ + SO ₄ ²⁻ + 3H ⁺ → 2CO ₂ + H ₂ S + 2H ₂ O	-63
CO ₂	C ₆ H ₁₂ O ₆ + 4H ₂ O → 2CH ₃ COO ⁻ + 2HCO ₃ ⁻ + 4H ₂ + 4H ⁺	-207
	2CH ₃ COO ⁻ + 2H ₂ O → 2CH ₄ + 2HCO ₃ ⁻	-31

**Fig. 5** Sequential reduction of oxidants (oxidized compounds) and accumulation of reductants (reduced compounds) in wetland soils. Adapted from Reddy RK, DeLaune RD, and Inglett PW (2022) Biogeochemistry of Wetlands: Science and Applications. 2nd edn. Boca Raton, FL, USA: CRC Press.

nitrate reduction to ammonia (DNRA), the reduction of nitrate to ammonium via nitrite ($\text{NO}_3^- \rightarrow \text{NO}_2^- \rightarrow \text{NH}_4^+$) (Reddy et al., 2022). Denitrifiers are a diverse group of heterotrophic bacteria (most of them facultative anaerobic), archaea, and fungi that couple the oxidation of substrates to the reduction of NO_3^- to either N_2O or N_2 . The process can be either organotrophic (organic electron donors including methane) or lithotrophic (inorganic electron donors such as Fe^{2+} or sulfide). This reaction occurs in moderately reduced conditions in the absence of oxygen and is one of the dominant mechanisms responsible for the loss of N from wetland soils. The rate of denitrification is largely determined by the concentration of NO_3^- as the electron acceptor. Dissimilatory reduction of NO_3^- is carried out by a diverse group of heterotrophic and facultative anaerobic chemolithoautotrophic bacteria. In anaerobic conditions, NO_3^- is first reduced to NO_2^- and then directly to NH_4^+ without being assimilated into microbial tissues.

Denitrification and DNRA are catalyzed by different strains of bacteria and Archaea, and their relative contribution to the overall nitrate reduction is often attributed to the availability of organic matter and the presence of sulfide, which has been shown to inhibit denitrification and stimulate DNRA. More recently, a variety of other reduced compounds have been shown capable of catalyzing NO_3^- reduction including Mn^{2+} , Fe^{2+} , and CH_4 . Other processes similar to denitrification have been identified. Among these are anaerobic ammonium oxidation (Anammox) which, as its name implies, involves NH_4^+ oxidation and the simultaneous reduction of NO_2^- to final product N_2 . Bacteria of the order Brocadiales including the genera Kuenenia, Brocadia, Jettenia, Candidatus Anammoxoglobus and Scalindua have been shown to possess hydrazine oxidoreductase, the enzyme required for Anammox. Measured rates have been reported in both estuarine and freshwater wetland soils, but N_2 production by Anammox is generally much lower than competing denitrification, thus its importance relative to other N cycling reactions is not well known.

The reduction of Fe and Mn in many soils is possibly one of the main processes of soil formation, and the relatively ubiquitous presence of Fe and Mn oxides in soils and sediments makes respiration by this pathway a major contributor of organic matter mineralization (Kappler et al., 2021). A large variety of microorganisms are capable of reducing Fe, including fungi. Fe^{3+} -reducing bacteria, including Geobacter and Shewanella species, couple the reduction of ferric iron with the oxidation of organic (fatty acids, carbohydrates, amino acids, aromatic compounds) or inorganic (dihydrogen, elemental sulfur, or sulfide) electron donors. When Fe^{3+} is reduced, Fe^{2+} is the reduced end product. Like Fe, Mn^{2+} is generally accepted as the end product of Mn^{4+} reduction though Mn^{3+} may also be encountered as an intermediate species. Fe^{3+} reducers can use complexed dissolved Fe^{3+} as well as short-range-ordered (e.g. ferrihydrite) or crystalline (e.g. goethite, hematite and magnetite) mineral phases as an electron acceptor, though the energy gained by such electron transfer varies depending on the mineral.

The redox potentials of diverse Fe(II)-Fe^{3+} redox couples lie between those of oxidized and reduced carbon, nitrogen, oxygen and sulfur redox species. Changes in solubility caused by Fe redox transformations also indirectly influence the mobility of other

elements with implications for the fate of carbon, nutrients (e.g., phosphorus) and contaminants (e.g., arsenic and cadmium). For example, Fe^{3+} readily complexes with available phosphate to lessen its availability. Upon reduction of Fe^{3+} to Fe^{2+} , however, phosphorus becomes more soluble leading to increased flux into the water column. More recently, oxidized forms of Fe^{3+} and Mn^{4+} were also shown to oxidize ammonium anaerobically in the processes Feammox and Mnammo, respectively (Reddy et al., 2022).

Sulfate reduction and oxidation processes are very important in wetlands affected by marine inputs of sulfur. Sulfate reducers are obligate anaerobes (bacteria and archaea) that couple the oxidation of a variety of organic substrates to CO_2 with the chemical reduction of the terminal electron acceptor SO_4^{2-} to sulfides ($-\text{S}^{2-}$) (Barton and Fauque, 2009). The strains isolated from rice paddy fields are mostly affiliated with the genera *Desulfovibrio* and *Desulfotomaculum*. Sulfate-reducing organisms do not synthesize enzymes to hydrolyze polymers such as polysaccharides. Also, many groups of sulfate-reducers cannot use monomers such as monosaccharides (e.g., glucose) as substrates for energy. Thus, sulfate reducers are mainly dependent on fermenters to produce simple organic compounds (e.g., acetate, propionate).

Sulfate reduction and oxidation frequently involves compounds and processes which are toxic to most organisms. For example, the product of sulfate reduction, hydrogen sulfide, is extremely toxic to aerobic organisms because it reacts with the heavy metal groups of the cytochrome system. Sulfate reducers are also responsible for converting mercury into the bioavailable methylated-Hg form. Hydrogen sulfide is very reactive with metals and usually results in the precipitation of metallic sulfides (e.g., FeS , ZnS , HgS), so in high sulfide areas toxic metals may be completely bound (and Hg methylation prevented). However, when these soils or sediments are exposed to oxygen (e.g., when dredged or coastal soils are drained) the sulfides are oxidized chemically and biologically (e.g., by *Thiobacillus ferrooxidans*) releasing the bound metals and lowering the pH through the formation of sulfuric acid $\text{H}_2\text{S} + 2\text{O}_2 \rightarrow \text{H}_2\text{SO}_4$.

Methanogens and Methanotrophs: The terminal step in the anaerobic degradation of organic macromolecules, in the absence of all other electron acceptors, is the conversion of acetate and H_2/CO_2 to methane (Conrad, 2007). Methanogens, typically found in the archaeal families of the *Methanobacteriales*, *Methanomicrobiales* and *Methanosarcinales*, are obligate anaerobes that can produce methane through the conversion of acetate to CH_4 and CO_2 (acetoclastic pathway) or through the conversion of H_2 and CO_2 to CH_4 (hydrogenotrophic pathway). Like sulfate reducers, methanogens cannot directly utilize large-molecular-weight polymers; so methanogens must depend on at least three groups of microbes, including hydrolytic, fermentative, and H_2 -producing acetogenic bacteria.

Sulfate reducers also consume acetate and H_2 and are direct competitors for substrates with methane. Thus, in areas of sufficient sulfate availability, methanogenesis can be completely inhibited. Once produced, methane can find its way to the atmosphere, but not all the CH_4 produced by methanogens is emitted into the atmosphere. Approximately half of the CH_4 is oxidized by methanotrophic microorganisms that live at the interface between anoxic and oxic zones. These organisms can be aerobic or anaerobic coupling the oxidation of CH_4 with the reduction of nitrate, Fe^{3+} , or sulfate compounds.

Agronomic, ecological and environmental significance

Anaerobic soils occupy an important niche in the biosphere, and their importance in wetlands and paddy rice soils is widely recognized by scientists, environmental managers, and policy-makers. Agronomically, anaerobic soils are widely used throughout the world for paddy rice production. Anaerobic wetland soils have unique biogeochemical properties and are primary drivers of the natural ecosystem function, as many of the processes have important feedback to ecosystem productivity and function. These soils are primary nutrient sources to plants grown in the paddy soils or wetlands. The decomposition process described here results in production of bioavailable nitrogen and phosphorus, which supports the productivity of plants. Furthermore, the extent of Fe^{3+} or Mn^{4+} reduction, or the presence of sulfide can strongly influence the distribution of toxic trace metals and availability of P.

Environmentally, anaerobic soils may have both positive and negative attributes. One negative aspect is that wetlands are one of the primary sources of greenhouse gas emissions including both nitrous oxide and methane. Nitrous oxide is produced during anaerobic nitrogen transformations such as nitrate reduction. Nitrogen loaded wetlands are therefore an important source of N_2O . Approximately 25% of methane emitted to the atmosphere is derived from wetlands (about $115\text{--}227 \text{ Tg CH}_4 \text{ year}^{-1}$). On a molecular basis and a time frame of 100 years, the global warming potential of CH_4 is about 25–40 times stronger than that of CO_2 . Disturbance and nutrient inputs can shift the balance of gaseous wetland C emissions toward CH_4 , therefore even though they accumulate organic matter, younger restored systems are more prone to have positive global warming potentials than older less impacted wetlands which emit a majority of CO_2 .

On the other hand, wetlands are very productive ecosystems and despite being only about 5–8% of the terrestrial landscape, serve as important terrestrial sinks of atmospheric CO_2 storing around 20–30% of the global SOC pool (around 650 Pg carbon). Natural wetlands, especially peatlands, generally accumulate C as a result of a greater rate of inputs (organic matter produced in situ and ex situ) than outputs (mainly slow decomposition of recalcitrant compounds under waterlogged conditions). There is growing evidence suggesting that organic matter turnover and stabilization in redoximorphic soils is also strongly linked to the dynamic interactions with redox-active minerals, in particular Fe oxyhydroxides. In northern peatlands wetland soil C is stabilized by cold temperatures and saturated conditions. Thus, climate change, and in particular warming, has a significant effect on boreal C storage where it both increases peat decomposition as well as enhancing releases of CH_4 from decomposition and thawing of frozen soils.

Anaerobic soils in wetlands are also highly valued for their function as sinks, sources, transformers of nutrients and contaminants, and their role in improving water quality. Wetlands and their significant storages of organic matter contribute significantly to

the export of necessary of secondary production for productivity of associated systems (e.g., fisheries). Wetland abundance and hydrological connectivity in watersheds is also a major contributor to pollutant and nutrient load reductions. This function of anaerobic soils has resulted in anaerobic soils or zones being incorporated in sustainable landscape designs (e.g., stormwater management) as well as low-cost constructed wetland technologies for water treatment. At present thousands of such wetlands are in operation throughout the world including a treatment wetland (360 ha) in arid climate at the Nimr Water Treatment Plant in Oman and the world's largest treatment wetland known as the Everglades Stormwater Treatment Areas system (Florida, USA) with more than 23,000 ha of total wetland area.

Abstract

Mineral-organic-microbial interactions drive many important biogeochemical reactions in soil environments. Microbial mineralization of soil organic matter (SOM) is an important process in which carbon (C) and nutrients are transformed to CO₂ and plant-available forms of nutrients that sustain life on the Earth. Microbes can solubilize, precipitate, and transform minerals and thus can have a significant influence on physical and chemical properties of minerals. There is an emerging view that microbial residues and dead microbial cells (or necromass) are involved in forming mineral-associated organic matter (MAOM), which is considered to be the main mechanism of OM stabilization in the soil. In this chapter we explore the complex interactions between OM and minerals and the role of the microbes in such interactions. Different procedures to isolate MAOM and various characterization techniques are discussed.

Key points

- Mineral-associated organic matter (MAOM) confers stability to organic carbon in the soil.
- Organic carbon in MAOM is mostly of microbially origin and the stabilization of organic matter in MAOM depends on the soil mineralogical properties, composition of the OM involved and environmental conditions in the soil.
- Iron and Al oxides, in particular their poorly crystalline forms, play a significant role in OM stabilization in soils due to their large specific surface area and highly reactive surfaces.
- Spectroscopic and micro-imaging techniques provide useful information about MAOM including the nature of interactions between mineral and organic compounds involved in MAOM formation.
- Mineral-organic-microbial interactions play a vital role in influencing agricultural sustainability and environment health.

Introduction

Minerals, organic matter (OM) and microorganisms are the constituents of the solid component of the soil. Soil organic matter (SOM) is a heterogeneous mixture originating from plants, animals and microbial residues. Soil OM is arguably the most dynamic, complex and least understood component of the soil. It represents the largest terrestrial carbon (C) pool, with variable size, composition and turnover time. Soil organic C (SOC) adsorbed to the reactive surfaces of soil minerals can be protected against biodegradation. This is an important natural process that preserves SOM, reduces CO₂ emission from soils, and provides benefits to crop productivity and many other soil ecosystem services. Several chemical processes are involved in the organo-mineral interactions and their stability are highly dependent on the composition of organic inputs, soil mineralogy, and environmental conditions. Soil minerals, including phyllosilicates, Fe and Al oxides, and short-range and poorly crystalline minerals, provide the reactive surface area for the adsorption of SOC. Organic C (OC) associated with minerals accounts for a major portion of the total SOC, and mineral-bound C has longer turnover times than the other fractions, such as free OM or physically protected OC in soil aggregates. Changes in the amount and stability of the OC associated with soil minerals, therefore, can have a significant influence on the bulk soil C storage in the long term and ultimately impact global warming and climate change.

In view of the significance of soil mineral-OM associations, this chapter presents an overview of the current knowledge of the proposed mechanisms, controlling factors and impact of organo-mineral interactions, as well as analytical techniques to investigate the interaction mechanisms. Important aspects of mineral-OM-microbiota interactions are also discussed.

Processes of organo-mineral interactions

Organic matter interacts with minerals through adsorption reactions on mineral surfaces and physical incorporation (occlusion) within soil aggregates. These interactions are defined by the intrinsic nature of the organic materials (e.g., their functional groups and molecular size), the type of minerals (e.g., 1:1 or 2:1 phyllosilicates or Fe oxides) and their surface properties (surface functional groups and specific surface area) as well as the soil properties (e.g., pH, type of cations, moisture status). The main mechanisms involved in the adsorption of OM to mineral surfaces are briefly described below and a schematic representation of these is given in Fig. 1.

Ligand exchange or inner-sphere complexation

A ligand exchange or substitution reaction is exactly what it says—a reaction in which one ligand in a complex ion is replaced by a different one; this mechanism is also called inner-sphere complexation or specific adsorption. Ligand exchange involves the exchange of acidic hydroxyl groups of OM (e.g., carboxyl and phenolic) with the hydroxyl groups on mineral surfaces. Ligand exchange occurs mostly in acidic soils containing Fe and Al oxides. It is one of the important mechanisms for the formation of organo-mineral associations, involving Fe (or Al)-O-C bonds.

Ion exchange

Organic cations such as protonated amines and quaternary ammonium cations can be adsorbed on to the surface of permanent charge clay minerals by cation exchange reactions or by forming outer-sphere complexes in soils (encircled-A in Fig. 1). The organic cations can exchange metal cations on the surfaces of clay minerals. Organic cations are often preferred over metal cations on soil exchange sites because of size considerations.

Polyvalent cation or water bridges

Negatively charged mineral surfaces repel organic anions, but binding occurs when a polyvalent cation is present on the exchange complex. Polyvalent cations neutralize the negative charge on the solid surface as well as the acidic group of the organic molecules

Fig. 1 Adsorption mechanisms of organic substances in three contrasting soils, (I) a Vertisol dominated by permanent charge mineral—smectite with small amounts of kaolinite and illite; (II) a Luvisol, containing hematite, goethite and phyllosilicates (smectite, illite and kaolinite); and (III) Thionic Fluvisol, consisting mostly of Fe oxides—ferrihydrate and goethite. Key mechanisms for organo-mineral interactions speculated in these soils are presented. The highlighted dotted-circled areas show—(A) electrostatic interactions (outer-sphere complexation), (B) polyvalent cation bridge, (C) Van der Waals forces, (D) hydrophobic interactions, (E) intercalation in the interlayers of expandable clay minerals, (F) inner-sphere complexation, and (G) co-precipitation in a poorly crystalline Fe oxide.

by forming a salt bridge, as shown in the encircled-B areas in Fig. 1. The predominant polyvalent cations in neutral and alkaline soils are Ca^{2+} and Mg^{2+} , whereas in acidic soils Fe^{3+} and Al^{3+} may exist in significant amounts. It has been suggested that higher valence cations, i.e., Fe^{3+} and Al^{3+} , form stronger coordination complexes than the lower valence cations, i.e., Ca^{2+} and Mg^{2+} .

Van der Waals forces

Van der Waals forces are weak electrostatic forces ($4\text{--}8 \text{ kJ mol}^{-1}$) that result from changes in the electric charge density of individual atoms. An electrically positive fluctuation in one atom causes an electrically negative fluctuation in a neighboring atom, resulting in a net attractive force. These forces are important in the adsorption of neutral polar and nonpolar molecules, particularly those with high molecular weight (encircled-C in Fig. 1).

Hydrogen bonding

When a hydrogen atom bonded to a strongly electronegative atom (e.g., an O—H bond in a water molecule) exists in the vicinity of another electronegative atom with a lone pair of electrons, hydrogen bonding is formed. For example, when a polar organic molecule or substance is unable to displace a water molecule solvating an exchangeable metal cation, it can attach directly coordinated water by forming a hydrogen bond. This type of arrangement is also referred to as 'water bridge,' where a water molecule acts as the link between an exchangeable metal cation and a polar organic molecule. Like Van der Waal's forces, hydrogen bonds are relatively weak ($2\text{--}40 \text{ kJ mol}^{-1}$) and not important for long-term protection of OM in soils or sediments.

Hydrophobic interactions

Nonpolar residues are excluded from water through entropy-related interactions, which force the nonpolar groups together. These interactions become abundant at low pH because of the protonation of carboxyl and hydroxyl groups of OM. These types of binding are less important for highly soluble low molecular weight organic acids and may be a dominant mechanism for larger macromolecules adsorption to mineral surfaces, although the bonding is very weak (4 kJ mol^{-1}).

Intercalation

Intercalation is a special type of adsorption of organic ligands within the interlayer spaces of expandable 2:1 phyllosilicates (as shown by encircled region E in Fig. 1), particularly at $\text{pH} < 5$. Organic cations can intercalate beyond the cation exchange capacity if Van der Waals forces play a major role in binding molecules to surfaces. Contrasting observations have been made about the intercalation of OM into interlayers of expandable phyllosilicates in acid soils ($\text{pH} < 4$). Because of the lack of specific methods to characterize and quantify intercalated OM, this issue has remained unresolved.

Co-precipitation

Co-precipitation of OM can occur when adequate metal (Al or Fe) and dissolved OM co-exist in certain soil environments, such as acid sulfate soils or soils that frequently experience periodic fluctuations in redox conditions, such as peat and wetlands. In this process a monomeric or polymeric aqueous metal species (Al or Fe) forms a mixed metal–organic solid from the solution after reacting with organic compounds (encircled-G in Fig. 1). This pathway may increase the potential quantity of mineral-associated OM per unit mineral surface compared to surface adsorption. For example, in a waterlogged paddy soil condition, coprecipitation resulted in greater OC contents ($49\text{--}213 \text{ mg g}^{-1}$) compared to adsorbed systems ($18\text{--}47 \text{ mg g}^{-1}$), and also enhanced the inclusion of OM within highly aggregated associations (Sodano et al., 2017).

Physical protection of SOM

Physical protection of SOM can occur through its incorporation into stable aggregates by the agglomeration or aggregation of the colloidal particles. Soil OM may act as a glue that holds inorganic soil particles together into aggregates. The aggregates can be grouped as macro ($>250 \mu\text{m}$)- or microaggregates ($<250 \mu\text{m}$) depending on their sizes. The initial unit of aggregation is called a microaggregate; it forms through the interaction of clay colloids with organic compounds and inorganic cementing materials. The microaggregates are bound together by organic compounds of different origins (e.g., plants or microbes) or structural binding agents (e.g., root hair and fungal hyphae). Aggregates of various sizes may also interact with one another in complex ways, conceptualized as the 'aggregate hierarchy' where aggregates form around microaggregates, and facilitate formation of additional macroaggregates, and mineral-associated OM (MAOM) within themselves. As a result of the occlusion of organics into large aggregates, their decomposition rate decreases, but to a lesser degree than the MAOM. Organic C in macroaggregates has a lifetime of only a few years whereas it is a century of lifetime for C in microaggregates. Soil aggregation and the protection of SOM are affected by several factors, including moisture content, clay content, mineralogy, and quantity and quality of OM in soils. The stability of aggregates is also affected by management practices; microaggregates are often formed as a result of disruption or decomposition of macroaggregates due to different management activities including tillage.

Mineral-organic matter-microbiota interactions

Soil microbial biomass constitutes about 5% of OM in the soil. Microorganisms live in the soil pore space, and therefore water content, pore-size distribution and pore inter-connectivity determine their abundance and activity in the soil. Soil microbial community structure and metabolic potential are greatly influenced by soil management ecosystems (e.g., arable, grassland and forest), environmental factors that influence C-input, and soil properties, such as soil pH, soil texture, mineralogy. Simultaneously, microbial-derived products and residues, such as, polysaccharides, proteins, cell wall polymers, and other organic molecules also become integral components of OM during formation, mobilization, transformation and storage of SOM. Thus, microbial community structure and composition, range and magnitude of the microbial activities, ability of microbes to metabolize or transform OM, and bioavailability of C substrates in OM are intimately connected, but these complex and highly dynamic interactions are still not well recognized.

Microorganisms interact with soil minerals in several ways, such as, microbially facilitated formation and dissolution of minerals, and formation of organo-mineral associations via the accumulation of microbial products on mineral surfaces, and ultimate acquisition and utilization of OM in organo-mineral associations for microbial metabolism (Kleber et al., 2015). Microorganisms have been shown to significantly facilitate weathering of minerals. Rhizosphere bacteria can directly solubilize minerals from soil. The mineral dissolution resulting from the microbial activity can be either an active or a collateral process. Free-living microorganisms and symbiotic fungi weather minerals through the formation of biofilms on their surface. The key mechanisms usually linked to bacterial weathering include pH changes adjacent to the mineral particle and proton promoted dissolution, chelation of elements present in a mineral matrix or the soil, and redox reactions (Samuels et al., 2020). Microbial weathering of mafic silicates, basalts, and glasses produce a variety of clay minerals, such as smectite, zeolite, and serpentine. Generally, microbes do not precipitate clay minerals directly, but the products of their weathering reactions reprecipitate to form clay minerals when surroundings become favorable.

A wide range of bacteria and archaea can reduce iron by typically attaching themselves to clay mineral surfaces (Dong 2012). An example of this is presented in Fig. 2, where Fe(III) in the structure of nontronite (an iron-rich smectite) is reduced by microbes, which is coupled with the oxidation of lactate to acetate. The reduction of structural Fe(III) to Fe(II) causes a decrease in the surface area, interlayer spacing, water swellability, and hydraulic conductivity of clay minerals. The reduction of structural Fe in smectite increases the negative layer charge and cation exchange capacity of the mineral, while the interlayer cations tend to be less exchangeable.

Microbial dissolution of minerals is demonstrated in Fig. 3, where *Shewanella putrefaciens* promotes the dissolution of nontronite (Perdrial et al., 2009). The authors hypothesized that the unstable octahedral Fe(III) at the edge of nontronite was complexed by the organic catecholate ligands and promoted the formation of Fe chelating agents, which enhanced the dissolution of nontronite (Fig. 3A). Subsequently, Ca^{2+} ions released (Fig. 3A) from the interlayers of the nontronite formed a bridge between bacteria and the nontronite surface, and later Si^{4+} was released (Fig. 3B) from the tetrahedral sheet of the mineral and precipitated as amorphous silica.

Microorganisms interact with minerals and metals for their own benefits. For example, prokaryotes use redox active metals as electron donors or acceptors to gain energy for growth. This leads to dissolution or precipitation of metals and this process ultimately influences the cycling of metals and fate of MAOM. Microbes also require metals for protein synthesis and have element specific sensory systems and uptake processes. For example, microorganisms can release siderophores to locate and chelate the

Fig. 2 Schematic diagram showing the structure of a 2:1 clay mineral nontronite (an iron-rich smectite) and microbial reduction of structural Fe(III) that is present in the octahedral sheet. The bioreduction of octahedral Fe(III) is coupled with the oxidation of lactate to acetate. Electron transfer is shown to take place parallel to the clay layers, but this does not exclude other possibilities. Based on Dong H (2012) Clay-microbe interactions and implications for environmental mitigation. *Elements* 8(2): 113–118.

Fig. 3 Schematic representation of the interaction of nontronite (an iron-rich smectite) and *Shewanella putrefaciens* at the lattice layer scale. (A) An octahedrally coordinated Fe(III) is mobilized at an unstable edge site and Ca²⁺ ion from is released from interlayer sites into solution. Bacterially produced ligands, catecholate, form siderophore complexes with Fe(III) as the central cation, and (B) released Ca²⁺ ions acts as a bridge between smectite and bacteria. The Fe(III) complex is transported to the cell, dismantled and reduced or involved in the formation of Fe(III)-coatings at the cell surface. As the complexation leads to continuous nontronite dissolution, Si is released and precipitated as amorphous silica, which is presumably associated with EPS. Based on Perdril JN, Warr LN, Perdril N, Lett MC and Elsass F (2009) Interaction between smectite and bacteria: Implications for bentonite as backfill material in the disposal of nuclear waste. *Chemical Geology* **264**(1–4): 281–294.

target metals from solid phases and transport them to the cell. To avoid adverse intracellular metal concentrations, microbes sometimes bind metals at the cell surface or in cytoplasm or on extracellular polymeric substances (EPS).

Generally, both the bacterial cells and mineral surfaces are negatively charged and bind to each other by forming a polyvalent cation bridge. Microbial cells can also bind to negatively charged surfaces of minerals through electrostatic forces when mineral colloids are coated with positively charged hydroxy polymers. Microbes produce EPS or cell peripherals like flagella or pili to adhere or attach to the mineral surfaces. EPS are composed of polysaccharides, proteins and lipids and have a very important role in the

interaction of minerals and OM in the soil. Preferential sorption of proteins on goethite, kaolinite and montmorillonite, and phosphate rich compounds and polysaccharides on Al hydroxides have been found. Microbe cell-connected siderophores can form inner sphere complexes between catechol groups and hydroxylated mineral surfaces. Also, Fe reducing bacteria can recognize Fe oxide surfaces and control surface attachment via outer membrane proteins.

Microbially produced enzymes can be easily adsorbed at mineral surfaces. Enzymes, like most proteins, are made up of amino acids with properties ranging from hydrophilic to hydrophobic, and carry negative, positive or no charge. Enzymes exhibit a strong affinity for soil mineral surfaces. In earlier studies, ionic exchange, electrostatic attraction, and entropic effects such as hydrophobic interactions were thought to be the main mode of bonding between enzymatic proteins and mineral surfaces. Interlayer adsorption of proteins on to the expandable clay minerals has also been considered in some instances. In some soils, short-range ordered or poorly crystalline metal oxides, such as Al and Fe oxides, may play a dominant role in regulating enzyme stability and activity.

Abiotic and biotic controls on soil organo-mineral interactions

Organic matter dynamics

Soil OM is a heterogeneous mixture of organic compounds of various origin, form and stability. Organic compounds in SOM can vary in molecular size, solubility, molecular complexity, aromaticity, aliphaticity and other properties. Generally, simple organic compounds, such as carbohydrates, amino acids, are easily mineralized with a short turnover time (labile) compared to complex compounds, such as, lignin and aromatics, with a longer turnover time (stable). The molecular variations in SOM originate from the source of origin and the decomposition stage of OM. Plant litter is the primary source for OM formation in soils. Soil microorganisms alter plant residues, resulting in changes in the chemical structure and synthesis of organic products of microbial origin. Cotrufo et al. (2013) proposed the 'microbial efficiency-matrix stabilization' framework for explaining the relation of plant litter input to the decomposition and formation of MAOM. The framework hypothesizes that soil microbial community mineralizes plant litter and the microbial products of decomposition then become the main precursors of MAOM, as shown in the left panel, microbial filter, in Fig. 4. The proficiency of MAOM formation is considered to be greatly affected by the litter quality, or in other words, substrate C use efficiency. The substrate use efficiency is greater for labile organic compounds, such as, carbohydrates and proteins, compared to the stable litter components like lignin. However, Mikutta et al. (2019) observed little effect of litter quality on the accumulation of MAOM. According to these authors, plant litter C can bypass microbial assimilation and be sorbed directly onto minerals to form MAOM, which is depicted in the right panel (mineral filter) in Fig. 4. The 'mineral filter' hypothesis assumes that POM and plant litter may generate dissolved OM which can be sorbed onto minerals in surface soils. From the dissolved OM,

Fig. 4 Two opposing hypotheses on pathways for the formation of mineral-associated organic matter (MAOM) in soils. According to the 'microbial filter' hypothesis (left) litter quality is the major driver for MAOM formation, with easily decomposable high-quality litter being preferentially assimilated by microorganisms due to higher substrate use efficiency and microbial assimilates then become sorbed to mineral surfaces. Low-quality litter with greater content of structural lignin components can accumulate in mineral soils as residual particulate organic matter (POM). The 'mineral filter' hypothesis (right) presumes that microbial degradation of plant litter and POM produces a wide spectrum of dissolved organic matter (DOM) components that interact with mineral surfaces. According to this hypothesis, both microbial and plant-derived OM components are involved in the MAOM formation. From Mikutta R, Turner S, Schippers A, Gentsch N, Meyer-Stüve S, Condron LM, Peltzer DA, Richardson SJ, Eger A, Hempel G and Kaiser K (2019) Microbial and abiotic controls on mineral-associated organic matter in soil profiles along an ecosystem gradient. *Scientific Reports* 9(1): 1–9.

phenolic and proteinaceous compounds are mentioned as preferentially sorbed to soil minerals, while the less strongly sorbed compounds, such as polysaccharides, are vertically transported to the sub-soil, where they may experience repeated sorption and remobilization cycles. Recently, Islam et al. (2022) postulated that the stabilization of OC into MAOM is a complex phenomenon that not only depends on the microbial C use efficiency of organic substrates but the abundance of active clay surfaces in soils. They postulated that microbial use and recycling of plant- and microbially-derived substrates decline with increased abundance of active clay surfaces. They further suggested that consideration of the interactions between biotic and abiotic controls on SOM stabilization is necessary to understand how efficiently C substrates of different chemistries are incorporated into MAOM in different soils.

The “humification” concept of forming a highly condensed macromolecular structure and the “selective preservation” concept of preferentially decomposing labile OM for forming stable OM in soils have been challenged in recent years. Lehmann and Kleber (2015) argued that “the available evidence does not support the formation of large-molecular-size and persistent ‘humic substances (HS)’ in soils” and proposed a new concept “soil continuum model (SCM)”. This concept indicates the importance of mineral-OM association for forming stable OM. According to this model, OM exists as a continuum of organic fragment sizes. The decomposition of large molecules leads to a decrease in the size of primary plant material with concurrent increases in polar and ionizable groups and thus to an increased solubility in water. At the same time, the chance for protection against further decomposition increases through greater reactivity towards mineral surfaces. In contrast, De Nobili et al. (2020) presented evidence to demonstrate that the SCM is not valid and that humification does occur along with synthesis of molecules that are not simply products of lysis of plant components. De Nobili and other researchers have argued that the SCM does not account for the complexity of SOM and does not consider the enormous amount of scientific literature that proves the high reactivity of plant and microbial metabolites.

Distinct affinity of minerals towards organic compounds has been shown based on the chemical composition of different mineral-organic associations (Kögel-Knabner et al., 2008; Yeasmin et al., 2014, 2017a). However, the information regarding the nature of MAOM is often inconsistent, with preferential association of aromatic C and protonated amide N with smectite and illite, polysaccharides with kaolinite, and aromatic and carboxylate C with Fe and Al oxides being observed.

Mineral phase properties

The soil clay fraction encompassing phyllosilicates, Fe and Al oxides, short-range-order Fe oxides, and poorly ordered aluminosilicates provides the majority of the surface area for the adsorption of OM in soils. Phyllosilicates are layered aluminosilicates with 1:1 and 2:1 unit layers which have different surfaces. The basal surfaces of 2:1 clay minerals (e.g., illite, smectite, vermiculite) consist of oxygen ions of the tetrahedral sheet, which carry permanent negative charge caused by isomorphic substitution (e.g., Al^{3+} for Si^{4+} in the tetrahedral sheet or Mg^{2+} for Al^{3+} in the octahedral sheet) in the mineral structure. The 1:1 layer phyllosilicates (e.g., kaolinite) are comprised of a tetrahedral and an octahedral sheet and have two types of basal surfaces, one consisting of basal oxygen ions of the tetrahedral sheet and the other made up of the hydroxyls attached to Al in the octahedral sheet. There is a little isomorphic substitution in the structure of 1:1 clay minerals. Both 2:1 and 1:1 phyllosilicates have variable charge developed on the surfaces at the broken edges of the minerals. Owing to the permanent negatively charged surfaces of 2:1 layer silicates, organic anions (e.g., carboxylates) are repelled from the surfaces and binding occurs through cation bridging only if polyvalent cations are present in soils. Cationic organic compounds (e.g., protonated amide) can interact directly with negatively charged phyllosilicate surfaces. Apolar organic compounds (e.g., alkyl C) can associate with hydrophobic basal surfaces of layer silicates through hydrophobic interactions. Organic compounds may also bind to phyllosilicate basal surfaces via weak interactions, such as Van der Waals forces and hydrogen bonding. The surface hydroxyls at the broken edges of layer silicates are positively charged under acidic conditions and associate with anionic organic molecules via ligand exchange. Non-expandable layer silicates, such as kaolinite, are believed to have only weak bonding affinities to organics due to the lack of layer charge and interlayer spaces on their surface compared with expandable 2:1 clay minerals such as smectites.

Iron and Al oxides carry variable surface charge. The hydroxyl groups on the oxide surfaces are positively charged in acidic soils and associate with anionic carboxyl groups of OM through ligand exchange. Organic molecules can also interact with Fe or Al oxide surfaces by forming hydrogen bonds and hydrophobic interactions. Soils, richer in oxide minerals (e.g., Ferralsols or Oxisols) and poorly crystalline aluminosilicates (e.g., Andosols), show greater C in MAOM than do soils richer in phyllosilicates (Yeasmin et al., 2017a). The significance of Fe and Al oxides in the OM stabilization in soils is demonstrated by a strong correlation between Fe oxide and SOM contents, reduction in the OM sorption after removal of Fe and Al oxides from soils and decreased mineralization of dissolved OM in the presence of Fe oxides.

Generally, short-range-order and poorly crystalline minerals of Fe, Al and aluminosilicates, (e.g. ferrihydrite, allophane) have a large ($>200 \text{ m}^2 \text{ g}^{-1}$) specific surface area (SSA); goethite, montmorillonite or illite have an intermediate SSA; but kaolinite and gibbsite have a much smaller SSA. The sorption of OC has been shown to increase with increasing SSA of soil minerals. The sorption of OC in the soil occurs preferentially at reactive sites, such as edges of phyllosilicates, particularly on Al—OH groups, rough surfaces (e.g., crystal surfaces of Fe oxides) or soil micropores. Due to preferential binding at the reactive sorption sites, the accumulation of OM at mineral surfaces occurs in patches instead of as a continuous coating. The patchy surface coverage by OM, however, is inconsistent with the use of SSA or micropores in predicting the amount of OM stabilized in MAOM in soils (Kögel-Knabner et al., 2008). The capacity of soils to stabilize OC can be restricted by OC saturation, which corresponds to the saturation of reactive sites on mineral surfaces. Using data from 84 sites in 27 countries, Fujisaki et al. (2018) determined the C saturation value in the fine fraction (MAOM) of tropical soils as 53 g C kg^{-1} , which is smaller than the global SOC storage value (78 g C kg^{-1}), which is based mostly on temperate soils. Fujisaki et al. (2018) also found the MAOM fractions very close to their SOC saturation capacity in forest soils as opposed to croplands.

It has been suggested that the organic molecules adsorbed first might be strongly stabilized via multiple ligand interactions. With increasing surface loading, sorption of newly added OC occurs with fewer ligand attachments, thereby leaving parts of unattached organic molecules that are more susceptible to degradation. Consequently, there is a greater potential for OM preservation in mineral rich sub-soils, as evidenced by a larger proportion of mineral bound OC held with stronger bonding than surface soils (Kögel-Knabner et al., 2008). However, less decomposition of SOM in sub-surface soils has also been explained by decreased microbial activity, resulting from reduced oxygen diffusion and lack of fresh organic residue input rather than the formation of MAOM. The stabilization of SOM in subsoil needs further research, particularly underlying mechanisms for the stabilization of SOM in MAOM. Keiluweit et al. (2017) observed that a shift in microbial metabolism to less efficient anaerobic respiration at anaerobic microsites, resulted in the selective accumulation in soil of reduced organic compounds, such as lipids and waxes. Quantitative data are needed to confirm the relationship between the abundance of anaerobic microsites and the amount of SOM stabilized or protected.

Soil solution chemistry

Differences in soil hydrological conditions, pH and ionic strength influence the formation and stock of MAOM in soils. For example, total adsorption of D-gluconic acid on gibbsite in 5 mM NaClO₄ solution was approximately tenfold greater at pH 9 and 12 than at pH 4 and 7 (Fig. 5, Schneckenburger et al., 2018). Changes in hydrological conditions can shift soil pH and redox conditions that can alter the reactivity of some soil minerals, such as, Fe and Al oxides. The potential of oxide minerals to stabilize OM is mostly relevant in acidic soils. The complexation of OM involving ligand exchange reactions on Fe oxides surfaces increases with decreasing solution pH (Yeasmin et al., 2014), which can be explained by the dissociation constant of the organic anions and increasing positively charged surfaces on oxides. Even under alkaline conditions Fe and Al oxides can possess a small positive surface charge and thus can bind anionic organic compounds. Additionally, an increase in ionic strength can enhance the adsorption of OM on minerals; this so-called 'salting-out effect' occurs due to a decrease in solubility of the nonelectrolyte in water in the presence of a salt.

Fig. 5 Sorption isotherms of aliphatic (poly)hydroxy carboxylic acid, D-gluconic acid, on gibbsite at four pH values, i.e., pH 4, 7, 9 and 12. Adsorption experiments were conducted using 5 mM NaClO₄ as the background solution. From Schneckenburger T, Riefstahl J and Fischer K (2018) Adsorption of aliphatic polyhydroxy carboxylic acids on gibbsite: pH dependency and importance of adsorbate structure. *Environmental Sciences Europe* 30(1): 1–15.

Insights into organo-mineral associations

Because of the complex nature of MAOM, the processes and mechanisms for their formation in different soil types are not well understood. The involvement of multiple mineral and organic phases of varying compositions and structures, and the existence several simultaneous abiotic and biotic reactions make the characterization of MAOM very difficult if not impossible. Different procedures have been used by researchers for the isolation and characterization of both organic and minerals phases present in MAOM, and some of the main procedures are given in Fig. 6.

Fig. 6 Schematic graph of physical (A and B), chemical (C) and combined chemical and physical (D and E) fractionation procedures of soil organic matter (SOM) (adapted from Poeplau C, Don A, Six J, Kaiser M, Benbi D, Chenu C, Cotrufo MF, Derrien D, Gioacchini P, Grand S and Gregorich E (2018) Isolating organic carbon fractions with varying turnover rates in temperate agricultural soils—A comprehensive method comparison. *Soil Biology and Biochemistry* **125**: 10–26). (A) Aggregates and particle fractionation: separated (i) SOM into aggregate size classes (macroaggregates >250 μm; microaggregates 250–53 μm; silt and clay <53 μm) by wet sieving yielded three particle fractions matching three classical fractions in texture analysis; and (ii) the second procedure isolated SOM into four particle sizes: particulate OM-POM-2000–200 μm (coarse sand), 200–50 μm (fine sand), 50–20 μm (coarse silt) and organo-mineral complexes (<20 μm). (B) Density fractionation: (i) procedure separated SOM into light fraction (LF; <1.6 g cm⁻³) and heavy fraction (HF; >1.6 g cm⁻³) by density fractionation using sodium polytungstate (SPT); and (ii) SOM separated into LF, and four HF consisting of organo-mineral complexes of different mineralogies. (C) Chemical fractionation: Oxidation separated fractions according to protection mechanisms i.e., mineral-protected and recalcitrant organic carbon. (D) Particle + oxidation procedure isolated SOM into >20 μm and <20 μm, and <20 μm fraction was treated with H₂O₂ to obtain H₂O₂ oxidation resistant SOM. (E) Particle + density + oxidation procedure: Isolated SOM into DOC = dissolved organic carbon, SC = silt + clay, rSOC = oxidation resistant organic carbon, POM, SA = stable aggregate that are related to the model pools of the Rothamsted carbon model. (F) Size + density fractions (based on Lavalley JM, Soong JL and Cotrufo MF (2019) Conceptualizing soil organic matter into particulate and mineral-associated forms to address global change in the 21st century. *Global Change Biology* **26**: 261–273): separates SOM into DOM = dissolved OM, water extractable, <0.45 μm, POM = particulate OM, not water extractable, >0.45 μm; light POM ≤1.60–1.85 g cm⁻³, heavy POM ≥1.85 g cm⁻³ and >53 μm, MAOM = mineral associated OM, >1.85 g cm⁻³ and <53 μm. The details of the references are given in Poeplau et al. (2018).

Isolation of mineral associated organic matter

Physical procedures

Physical fractionation procedures involve various degree of soil dispersion, followed by density or size separation (Fig. 6A and B) to isolate pools of SOM associated with minerals of different sizes and density. Organic substances isolated using these procedures have been useful to study the interactions between organic and mineral components of soils and the fractions have been related to the turnover of SOM.

Particle size fractionation

Particle size fractionation (Fig. 6A) is based on the concept that SOM associated with particles of different sizes and different mineralogical composition varies in its structure and function. Generally, quartz is the dominant mineral in the sand fraction whereas phyllosilicates and Fe or Al oxides are abundant in the clay fraction of soils. A meta-analysis of the typical allocation of OM in particle size fractions of temperate arable top-soils show about 50–70% of the total SOC is associated with the clay fraction ($<2\ \mu\text{m}$), 20–40% with the silt fraction ($2\text{--}63\ \mu\text{m}$) and $<10\%$ with the sand fraction ($>63\ \mu\text{m}$) (von Lützow et al., 2007). The greater association of SOC with smaller particles does not always correspond with a longer turnover time. von Lützow et al. (2007) reported a shorter turnover time range (76–190 years) for SOC associated with the clay fraction compared to the OC associated with the silt (115–676 years) and sand (0.5–374 years) fractions. Therefore, particle size fractions may provide a crude measure of the composition and turnover time of OM associated with different size fractions.

Density fractionation

Density fractionation (Fig. 6B) is used to isolate free or unassociated OM (light fraction) from MAOM (heavy fraction) in soils. Soil OM typically has density varying between 1.24 and $1.64\ \text{g cm}^{-3}$ and soil minerals have a particle density greater than $1.6\ \text{g cm}^{-3}$. Aqueous solutions of various inorganic salts, such as, magnesium sulfate (MgSO_4), zinc bromide (ZnBr_2), sodium iodide (NaI), and sodium polytungstate ($\text{Na}_6(\text{H}_2\text{W}_{12}\text{O}_{40})$), have been commonly used for the density fractionation of SOM. Sodium polytungstate is the most widely used, since a wide range of densities can be obtained using the salt (from 1.0 to $3.1\ \text{g cm}^{-3}$) and it has a low viscosity, little toxicity and can be easily recycled. The light fractions of SOM contain predominantly easily decomposable plant residues, whereas the heavy fractions comprise MAOM, with highly decomposed stable OM. However, the presence of charred material, in addition to the plant litter, in the light fraction has also been reported, which can lead to the overestimation of the OM in the light fraction and underestimation of MAOM in the heavy fractions.

Separating SOM into multiple sequential density fractions has also been used to isolate OM associated with individual clay minerals, with the aim to investigate the interaction mechanism and composition of OM associated with individual mineral matrices in the density fractions (Sollins et al., 2009; Jones and Singh, 2014; Yeasmin et al., 2017a). Generally, OM associated with phyllosilicates is present in the density fraction between 1.8 and $2.6\ \text{g cm}^{-3}$ and with Fe oxides in density fractions $>1.8\ \text{g cm}^{-3}$ (Yeasmin et al., 2017a). Nevertheless, sequential density fractionation is a useful procedure to determine OM-mineral associations and OC turnover dynamics in MAOM.

Chemical procedures

Chemical isolation procedures involve either a selective oxidation of SOM or selective dissolution of mineral phases to characterize SOM.

Oxidation of SOM

Soil OM can be oxidized using reagents, such as hydrogen peroxide (H_2O_2), sodium hypochlorite (NaOCl), potassium permanganate (KMnO_4), and sodium persulfate ($\text{Na}_2\text{S}_2\text{O}_8$), all of which remove easily decomposable or labile OM and leave behind a relatively stable OM fraction in the residues. The chemical oxidation is expected to mimic the biodegradation of SOM under natural conditions. Among the SOM oxidizing reagents, NaOCl is preferred for isolating the labile and stable MAOM because of the oxidation efficiency and minimal effects on soil minerals (Mikutta et al., 2005, Fig. 6C). The removal of about 26–96% of OC from soils with different mineralogies, and 77–95% of the initial OC from 196 mineral soil fractions by oxidation with NaOCl support the potential of this reagent to separate OM associated with minerals (Kaiser and Guggenberger, 2003). The residues of NaOCl treated OM were characterized by the presence of aromatic and alkyl C, which had been sequestered for a longer time than that released by other oxidants (Mikutta et al., 2005; Yeasmin et al., 2017a). Whether the isolated residues represent the stable SOM pool, due to the selective oxidation of labile organic compounds or due to the association of certain SOM substances with the mineral matrix, still needs further investigation.

Dissolution of minerals

Hydrofluoric acid (HF) has been used to isolate MAOM by the dissolution of silicates, carbonates and metal oxides. Dissolution of total OC up to 57% in the mineral rich sub-surface soil horizons led to the conclusion that HF dissolves the MAOM fractions (Rumpel et al., 2008). However, the mineral removal efficiency from soils and the composition of dissolved OM with the HF treatment can vary with soil types and depth. In general, the HF soluble OM fraction was found to be older OC than the HF resistant OM that was left in the residues. Yeasmin et al. (2017b) found the HF treatment to be better than NaOCl and dry ashing treatments for characterizing SOC using IR spectroscopy, the HF treatment rendered mineral interference-free spectra with relatively least

affected and accentuated organic bands. The authors also pointed that HF treated spectra may reflect the total OC qualitatively, but one should be careful in using spectra for quantitative analysis after the HF treatment, particularly in mineral rich soils.

Combination of physical and chemical procedures

Combined physical and chemical fractionation procedures (Fig. 6D–F) have been used to overcome the limitation of the individual physical or chemical procedures. In this approach, physical fractions are expected to capture the spatial arrangement of different MAOM particles, whereas the chemical isolation can be suitable for elucidating the molecular-level interactions between SOM and minerals. Various schemes have been employed combining physical and chemical procedures, e.g., size or density fractions followed by oxidation or acid hydrolysis. Yeasmin et al. (2017a) used a combined procedure of physical (sequential density fractionation) and chemical (NaOCl, HF) to examine the role of minerals in protecting OC in four different soil types (Ferralsol, Luvisol, Vertisol and Solonetz) (Fig. 7). They effectively isolated MAOM into three distinct groups in the soils: (i) OM associated with Fe and Al oxides (1.8 to >2.6 g cm⁻³ in the Ferralsol); (ii) OM associated with phyllosilicates (1.8 – 2.6 g cm⁻³) and (iii) OM associated with quartz and feldspar (>2.6 g cm⁻³) in the Luvisol, Vertisol and Solonetz by a sequential density fractionation procedure. Later, after chemical fractionations, it was observed that the Fe and Al oxides dominated fractions were relatively more resistant to NaOCl oxidation and more OC was dissolved with the HF treatment than other fractions, which suggests that OC is protected better against oxidative degradation in MAOM formed in association with Fe or Al oxides than MAOM formed in association with phyllosilicates, and quartz and feldspar matrices.

Poeplau et al. (2018) evaluated 20 different SOC fractionation methods for their suitability to isolate fractions with varying turnover rates, using agricultural soils with vegetation change from C₃ to C₄. Based on different criteria, including differentiation, redundancy, recovery, reproducibility, workload, and overall performance indicators, they identified five best methods and among them three methods used combined physical and chemical approaches, i.e., particulate + density, aggregate + oxidation, and particulate + density + oxidation.

Thus, combinations of physical and chemical procedures have been found to be more effective in isolating the MAOM fractions than a single method. Physical isolates represent the effects of the spatial arrangement of primary and secondary organo-mineral associations on SOM dynamics, whereas the chemical fractions are more appropriate to explicate molecular-level interactions between OM and mineral particles in the soil (von Lütow et al., 2007). Preceding spatial separation of the discrete mineral-OC assemblages by physical fractionation might facilitate the chemical treatments to produce more homogenous OC fractions.

Fig. 7 A conceptual model showing the qualitative and quantitative composition of organic carbon (OC) across different density fractions with varying proportion of phyllosilicates (kaolinite, illite and smectite), Fe or Al oxides (hematite, goethite and gibbsite) and primary minerals (quartz and feldspars) in four soil types, and changes after organic matter oxidation using NaOCl and HF demineralization. By comparing the residuals, it was observed that the size and composition of labile and preserved OC pools were greatly influenced by the abundance and surface properties of soil minerals. The points of cones and arrows indicate the direction of change between density fractions and the thickness of the cones indicate the magnitude of change (increase or decrease). Specific colors assigned to different fractions and the same color represents the same fraction in the properties' panels. From Yeasmin S, Singh B, Johnston CT and Sparks DL (2017a) Organic carbon characteristics in density fractions of soils with contrasting mineralogies. *Geochimica et Cosmochimica Acta* **218**: 215–236.

Characterization of mineral associated organic matter

The chemical composition of OM associated with minerals in the isolated OM fractions and laboratory prepared complexes of organo-mineral complexes can be examined directly using advanced techniques, such as spectroscopic techniques, use of stable isotopes and radiocarbon, and microbial markers. Among the spectroscopic methods, solid state ^{13}C nuclear magnetic resonance (NMR) is considered to be the gold-standard for SOM characterization. In addition to NMR, Fourier transform infrared (FTIR), X-ray photoelectron spectroscopy (XPS) and isotopic ratio mass spectroscopy (IRMS) are widely acknowledged for SOM characterization. Using these techniques, samples can be analyzed without major pre-treatment and extraction.

NMR spectroscopy

In the solid-state ^{13}C NMR spectroscopy, ^{13}C nuclei found in various functional groups of SOM are distinguished on the basis of 'chemical shift' regions of the magnetic field of the spectrometer. Each chemically distinct C functional group has a characteristic chemical shift region, e.g., alkyl C = 0–45 ppm, O/N-alkyl C = 45–110 ppm, aromatic C = 110–160 ppm. By integrating the signal intensity contained within each chemical shift region, the proportion of different C groups can be determined. NMR analysis is very useful in identifying the state of OM biodegradation in the samples using the ratio of alkyl to O-alkyl C and aromaticity. This technique has the potential to distinguish between charred and lignin derived aromatic C, which is not possible with DRIFT spectroscopy. However, this technique has some drawbacks—it is not very sensitive for samples with low OC, it causes low resolution and low signal to noise ratios of spectra, and there can be interference of paramagnetic species present in the soil. The mineral interference in soils can be overcome via dissolution of minerals with HF.

Solid-state ^{13}C NMR spectroscopy is generally used to determine the proportions of the main functional groups of SOMs in whole soil samples and in isolated physical fractions of soils. Poirier et al. (2005) compared the chemical composition of the density separated SOM fractions (free POM, aggregate occluded POM and MAOM) by using a range of spectroscopic methods including NMR (Fig. 8). NMR spectroscopy data showed that free POM was dominated by carbohydrates, while aggregate-occluded POM was dominated by aromatic signals (Fig. 8). Both OM fractions had weaker alkyl and carboxyl signals than MAOM, but exhibited almost similar abundance of N-alkyl, acetal and phenolics. Large contributions of carbohydrates, O-alkyls and aromatics

Fig. 8 Solid-state ^{13}C NMR spectra of (A) free particulate organic matter (POM), (B) aggregate-occluded POM and (C) mineral-associated OM fractions of a Chromic Luvisol from the Broadbalk experiment at Rothamsted in the UK. From Poirier N, Sohi SP, Gaunt JL, Mahieu N, Randall EW, Powlson DS and Evershed RP (2005) The chemical composition of measurable soil organic matter pools. *Organic Geochemistry* **36**(8): 1174–1189.

were prominent in the MAOM fractions. The ratio of peak area in the O-alkyl relative to alkyl C regions was 4.06, 3.01 and 0.86 for free POM, aggregate occluded POM and MAOM, respectively, which suggests that MAOM with a smaller ratio has experienced greater decomposition than the other two fractions.

FTIR spectroscopy

FTIR spectroscopy has proven to be an extremely valuable tool in determining SOM chemistry and elucidating binding mechanisms involved in MAOM formations. FTIR spectroscopy uses polychromatic radiation to measure the excitation of molecular bonds and the relative absorbance of different bands provide an index of the abundance of various functional groups. A variety of FTIR techniques have been used to investigate organic-mineral interactions, e.g., transmission FTIR; diffuse reflectance infrared Fourier transform (DRIFT); attenuated total reflectance (ATR)-FTIR. ATR-FTIR spectroscopy is the most powerful technique to study the molecular level interfacial organic chemistry on mineral surfaces due to its high sensitivity to a small molecular change in the medium. Indications of different coordination complexes of organic compounds on mineral surfaces and the types of surface complex structures formed can be obtained from FTIR spectra. Formation of inner-sphere complexes between organics with a carboxylic group and mineral surfaces is often designated by substantial shifts in the frequency of asymmetric and symmetric COO^- stretching relative to a spectrum of the aqueous solution.

For example, an ATR-FTIR study of glutamate sorption on rutile by Parikh et al. (2011) indicated three potential surface configurations: bridging bidentate through inner-sphere coordination of both carboxyl groups, chelating monodentate via inner-sphere coordination of the γ -carboxyl and bridging bidentate with inner-sphere coordination of the α -carboxyl and outer-sphere coordination of the γ -carboxyl. Yeasmin et al. (2014) also made an ATR-FTIR study of carboxylic (citric and oxalic) and amino (glutamic, alanine, phenylalanine and lysine) acid sorption on kaolinite, illite, montmorillonite, ferrihydrite and goethite. Their results indicated that citric and oxalic acids possibly formed monodentate or bidentate inner-sphere, and outer-sphere complexes with Fe oxide and kaolinite surfaces. Iron oxides interacted with amino acids via the carboxylate group, whereas amino groups or both carboxylate and amino groups were involved in the sorption on phyllosilicates. Amino acids sorbed to the minerals mostly via electrostatic interaction or H-bond or Van der Waals interaction.

DRIFT spectroscopy is the most commonly used method for characterization of SOM because it is a quick and nondestructive technique. DRIFT spectral data can also be used to identify and quantify the presence of important organic functional groups such as aliphatic-C, aromatic-C, carboxyl-C in SOM fractions. Recent work has also shown the usefulness of the band ratio approach as an indicator for characterizing the decomposability of the SOM, such as the ratio of carboxylate to polysaccharides and the ratio of aromatic to aliphatic bands. Fractionated samples have been investigated to delineate the chemistry of OC associated with different mineral surfaces. Yeasmin et al. (2017a) found that oxidation resistant and HF soluble OC of the phyllosilicate-dominated fractions were enriched with aromatic-C, polysaccharides and amide-N; OM associated with Fe and Al oxides was predominantly aromatic- and carboxylate-C; and quartz and feldspars associated OM was comprised of N-containing organic compounds and polysaccharides. However, the application of DRIFT spectroscopy to characterize the composition of OM fractions can be compromised by the interference of mineral absorbance in the sample.

X-ray photoelectron spectroscopy

X-ray photoelectron spectroscopy (XPS) provides a direct chemical analysis of mineral surfaces without any extraction procedure. It consists of exposing a surface to a soft X-ray beam (typically ~ 1.5 keV) to induce the ejection of photoelectrons from the atoms present in this surface. The kinetic energy of the ejected electrons is measured, and the electron binding energy of the emitting atom is calculated as the difference between the known energy of the X-ray and the kinetic energy. It records a spectrum of electron binding energy and each peak of the spectrum is characteristic of a given energy level of an element. Due to inelastic scattering of the electron in the sample, XPS provides information about the outermost 2–10 nm layer only. This technique can distinguish between different bonding environments of C, N and O by measuring the shift in the electron binding energy with electron density (oxidation state) of the emitting atom. Jones and Singh (2014) determined carboxylate functional groups and Fe concentration in six density fractions of four soil types and found a strong positive correlation between the abundance of carboxylate functional groups and the Fe concentration in soil density fractions (Fig. 9). The authors speculated that OM is bonded strongly via carboxylate groups to Fe oxides surfaces. These results show the important role of Fe oxides in the preservation of SOM in a variety of soils.

Natural carbon isotope

Since plant residues are the main source of SOC, its isotopic signature resembles the vegetation from which it has been derived. During the microbial decomposition of plant residues, the $\delta^{13}\text{C}$ value increases. Thus, stable isotope analysis ($\delta^{13}\text{C}$ and also $\delta^{15}\text{N}$) acts as a powerful tool to assess the source and also the degree of microbial transformation of SOM or OM fractions in the soil. Generally, larger $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values are reported to be associated with longer turnover times for MAOM than the plant residues, which suggest the stabilization of microbially transformed OM on mineral surfaces.

Radiocarbon dating

Radiocarbon dating of SOM can be done by in situ labelling with the 'bomb' ^{14}C approach, based on the enrichment of ^{14}C in the atmosphere due to the atmospheric testing of nuclear weapons in the 1950s and 1960s. The information on the degree to which this 'bomb' ^{14}C is found in SOC helps to differentiate OC pools with different turnover rates, ranging from seasonal to millennial time scales. The ^{14}C contents are calculated from the measured $^{14}\text{C}/^{12}\text{C}$ ratio of the sample compared to that of an international standard

Fig. 9 The relationship between log transformed Fe concentration (% w/w) and proportion of O=C—O functional groups derived from the XPS analysis of six density fractions i.e., <1.6, 1.6–1.8, 1.8–2.0, 2.0–2.2, 2.2–2.6 and >2.6 g cm⁻³ of four contrasting soils from New South Wales, Australia. From Jones E and Singh B (2014) Organo-mineral interactions in contrasting soils under natural vegetation. *Frontiers in Environmental Science* 2: 2.

from 1950. The primary modern radiocarbon standard is oxalic acid I, 95% of the activity of the oxalic acid I is equal to 100 pMC (percent Modern C) or to a hypothetically ¹⁴C-activity from the year 1950. ¹⁴C values greater than 100 pMC indicate the presence of bomb-produced ¹⁴C, and lower values indicate the predominance of C fixed from the atmosphere long enough ago for significant radioactive decay of ¹⁴C to have occurred. The ¹⁴C age of different MAOM fractions may be indicative of the mechanisms that cause OC to persist in soils over millennial time scales.

Generally, MAOM fractions (HF dissolved or oxidation resistant OM) have been found to contain older OC than the free OM (HF resistant or oxidized OM) (Rumpel et al., 2008). However, MAOM fractions do not necessarily always contain old C. For example, a radiocarbon measurement of extracted mineral-associated OM pools found recently deposited plant inputs (modern $\Delta^{14}\text{C}$) in the mineral protected OM (Mikutta et al., 2006). The age of OM may vary depending on the mineral properties and association of OM in organo-metal complexes or mineral-associated OM. Identical age for OM in MAOM and free OM or particulate OM has also been found in soils.

Micro-imaging

Scanning electron microscopy (SEM) and transmission electron microscopy (TEM) are useful techniques for obtaining information about the shape and size of OM and minerals, however, because of the high vacuum and beam damage to samples, these techniques are not useful for characterization of SOM and MAOM. Atomic force microscopy (AFM) can determine the topography of surfaces as well as the bonding type and mechanical properties of the surface. Dynamic force spectroscopy (DFS) uses a functionalized AFM cantilever, which is allowed to interact with a surface so that a bond between the functionalized tip and the surface is formed. This in situ technique has also been used to make quantitative molecular scale measurements of OM bound to a mineral surface (Newcomb et al., 2017). These authors showed that DFS can perform on pristine, flat as well as on heterogeneous mineral surfaces. This technique is suited to measure the binding strength of biomolecules at OM-mineral interfaces even during biological activity, such as in the presence of enzymes or live microbes (Newcomb et al., 2017). Additionally, these authors showed monolayer adsorption of organics on mineral surfaces as the mechanism of organo-mineral associations, which is contrary to the theory of heterogeneously multilayered distribution of OM on mineral surfaces.

Synchrotron-based techniques

Synchrotron-based approaches are useful to study the mineral-OM associations. Scanning transmission X-ray microscope (STXM) combined with near-edge X-ray absorption fine structure (NEXAFS) spectroscopy has been used to explore microscale heterogeneity of OM within a soil aggregate and on mineral surfaces. STXM and NEXAFS spectroscopy were further combined with isotopic sensitive high resolution secondary ion mass spectrometry (SIMS) imaging to investigate the formation, heterogeneity and potential importance of newly formed mineral-OM associations over time (Vogel et al., 2014). Quantitative NanoSIMS results (Vogel et al., 2014) revealed that almost all the OM existed in the clay-sized fraction and was bound in mineral clusters. A preferential association of new OM was found with organo-mineral clusters with rough surfaces containing pre-existing OM. This is confirmed by an increase in area enriched in ¹³C and ¹⁵N, while the total area was covered with a constant amount of OM. Additionally, only a partial percentage of the total clay-sized mineral particles were involved in OM sequestration, which was unexpected for clay-sized mineral particles (illite, mixed-layer clay minerals and pedogenic iron oxides, such as goethite) in this soil with reactive surfaces.

Chen et al. (2014) investigated C associations with Ca, Fe, Al, and Si species in the clay fraction of soils from an upland pasture hillslope using STXM-NEXAFS spectroscopy. Chemical imaging and NEXAFS spectra were obtained using image sequence scans over

Fig. 10 Carbon image difference maps ($OD_{289}-OD_{282}$) of the thin regions from the (A) summit and (B) footslope soil clay particles. The gray scale indicates thickness in nanometers. C 1s cluster indices map showing the distribution of C functional groups in the thin regions from the (C) summit soil clay particles, with three distinct regions (red, green, and blue) and (D) footslope soil clay particles, with two distinct regions (green and blue). The C 1s NEXAFS spectra were extracted from the regions in the cluster indices maps for the (E) summit and (F) footslope soil clay particles, respectively. Note the color of the spectra and the region's color from which they were extracted are the same. Spectra features identified by the vertical dashed lines correspond to (i) aromatic (C=C) (285.5 eV), (ii) aliphatic C—H (287.4 eV), (iii) carboxylic (COOH) (288.6 eV), and (iv) polysaccharides C—OH (289.5 eV) functional groups. The peaks at higher energies are from K and correspond to its L_3 and L_2 edges. Correlation coefficients values of C with different elements within distribution maps of the summit and footslope soil clay particles are given in Ci and Di, respectively. From Chen C, Dynes JJ, Wang J, Karunakaran C and Sparks DL (2014) Soft X-ray spectroscopy study of mineral-organic matter associations in pasture soil clay fractions. *Environmental Science and Technology* 48(12): 6678–6686.

a range of photon energies covering C 1s, Ca 2p, Fe 2p, Al 1s and Si 1s edges (Fig. 10). The C distribution map was obtained by subtracting the below-edge optical density ($OD = \ln(I_0/I)$, I = transmitted flux through the sample and I_0 = incident flux measured in an empty region adjacent to the analyzed particles) map from its above-edge OD map and showed fine-scale heterogeneity in the compositional chemistry of organic C of summit and footslope soil clays (Fig. 10C and D). Three (red, green, and blue) and two (green, blue) distinct regions were identified in the summit and footslope soils, respectively using principal component analysis (PCA) and cluster analysis (CA). The C NEXAFS analyses show that in both soil clays aromatic-C, carboxyl-C, and polysaccharides were prevalent, with the relative abundance of carboxyl-C and polysaccharides varying spatially at the sub-micrometer scale. Only the clay fraction of the summit soil showed the presence of aliphatic-C, which is indicated by the red region in Fig. 10C and the corresponding spectrum in Fig. 10E shows a peak at 287.4 eV for aliphatic-C. The results further showed that C was associated with Ca, Fe, Al, and Si and there was no discrete phase of C. Carbon was associated with both Fe oxides and aluminosilicate minerals (Chen et al., 2014). The study demonstrates progress being made in the compositional chemistry and associative interactions between OM and natural minerals at the sub-micrometer scale.

Organo-mineral interactions and terrestrial environment

Soil ecosystem services

Soil structural stability

Soil OM turnover is intimately associated with soil structure. The aggregation of fundamental soil particles not only distribute OM heterogeneously, but it also produces various reaction sites and pathways, and environmental conditions in the soil. Soil structure results from the bonding of elementary soil particles by cementing substances such as root exudates, microbial products and other organic substances, Al or Fe-oxides, colloidal silica and calcium carbonates. Both biotic and abiotic processes contribute to soil aggregation and structural stability. Biotic processes, such as plant exudates and plant roots, macrofauna when they ingest organic and mineral soil components together, and microbes by acting on their close organo-mineral environment, all have significant role in soil aggregation. Organo-mineral associations can be considered as structural units of soil aggregates and the nanoparticulate fraction of soil microaggregates. The important role of short-range ordered phases of Fe, Mn, and Al in MAOM is well recognized and thus their role in the formation and stabilization of soil aggregates is central as well. Abiotic C stabilization mechanisms in soil are strongly related to biotic mechanisms. The mechanisms in the formation of micro- and macro-aggregates might be different, which may lead to contrasting OM mineralization rates in soils. Other factors such as existence of different microbial communities in micro- and macro-aggregates, and the differences in the composition of OM and stability of micro- and macro-aggregates can also regulate the mineralization of OM.

Several novel techniques allow insight into mechanisms and processes involved soil aggregation and the formation soil structure, which influences OM mineralization. Imaging techniques like X-ray microtomography (μ CT) can provide details of the physical structure, including pore size distribution, pore connectivity and distances between pores and occluded particulate OM in undisturbed soil, at a spatial resolution of a few microns. Nanoscale secondary ion mass spectrometry (nanoSIMS) and synchrotron based STXM-NEXAFS spectroscopy not only can locate OM at the sub-micrometer scale, but also provide chemical and structural information. These novel techniques, in combination with traditional experimental methods are expected to improve our understanding on the role of soil structure on OM dynamics and incorporating the drivers into emerging C models.

Biochemical cycling of nutrients in soil

Organic matter is a reservoir of nutrients, and its turnover is central to nutrient cycling in the soil. The turnover of OC is often closely associated with the dynamics of N, P and S in the soil. The relationship between nutrients and SOM mineralization is not straightforward, as microbes need nutrients to degrade SOM. Therefore, the addition of nutrients in the soil can result in a decrease or an increase in OM, depending on the initial SOM stoichiometry, the formation MAOM incorporating the microbial products of decomposition, and the simultaneous effects on plant productivity and OM inputs to soils. Overall, net gain or loss in the SOM (and the preservation and availability of nutrients) depends on interactions between the soil mineral matrix, plants, and microbes (Cotrufo et al., 2013). Thus, C:N:P:S stoichiometry is important in SOM cycling and there are suggestions to include this in future C models.

Mobility and bioavailability of heavy metals

Heavy metal pollution has been a global problem which presents a severe threat to the environment and human health. The mobility and biotoxicity of heavy metals depend on their speciation in terrestrial and aquatic environments, particularly their associations with solid fractions of soils including OM. These biotic and abiotic components naturally interact with each other to form MAOM composites, complexes or aggregates involving various processes, such as adsorption, coating and co-precipitation. These interactions have profound control on the speciation, mobility, bioavailability and ultimately the fate of heavy metals in soils and sediments.

Humic acid (HA) and fulvic acid (FA) form complexes with soil minerals via their surface carboxylic and hydroxyl groups, hydrogen bonds and hydrophobic forces. These complex interfacial reactions significantly influence the retention and release of heavy metals in soil environments. Generally, there is increase in the adsorption of heavy metals in the presence of HA and FA. The increased metal adsorption has been attributed to the decreased surface potential of Fe (hydr)oxides induced by HS, changes in affinity of HS for heavy metals or the formation of ternary composites. The interfacial interactions between Fe (hydr)oxides and HA associations strongly influence the immobilization and transport of heavy metals, particularly in acid soils in tropical and subtropical regions, acid sulfate soils and acid mine sediments.

Organic compounds accelerate the adsorption rate of heavy metals and increase the adsorption capacity to the solid assemblages in soils in comparison to pure minerals. For example, Engel et al. (2021) observed up to three times greater adsorption of Cd, Zn and Ni on organic-ferrihydrite assemblages compared to metal adsorption on pristine ferrihydrite (Fig. 11).

Du et al. (2018a, 2018b) investigated the adsorption behavior of Pb and Cd on iron-humic acid composites formed by adsorption (adsorption of OM on pre-synthesized ferrihydrite) and coprecipitation (formation of ferrihydrite in the presence of HA). The ferrihydrite-HA coprecipitated composites have a greater C content and smaller surface area compared to the equivalent adsorbed composites. They found a faster adsorption rate of Pb on co-precipitated ferrihydrite-HA composites than the Fe-OM composites made by OM adsorption. In a study of As(V) adsorption onto Fe-humic composites formed by adsorption and co-precipitation at different Fe:C ratios, the fastest reaction was observed on the co-precipitates formed at high C content, which

Fig. 11 A schematic representation of the effects of organic compounds on the sorption of heavy metals (Cd, Zn and Ni) on ferrihydrite. The sorption rate and the binding capacity of metals on ferrihydrite increased in the presence of organic compounds. The metal loading order on ferrihydrite was also changed, in pristine ferrihydrite (i.e., without organic compounds) the metal loading followed the order: $\text{Ni} > \text{Zn} > \text{Cd}$, which changed to $\text{Cd} > \text{Zn} > \text{Ni}$ in the presence of organic compound. From Engel M, Pacheco JSL, Noël V, Boye K and Fendorf S (2021) Organic compounds alter the preference and rates of heavy metal adsorption on ferrihydrite. *Science of the Total Environment* **750**: 141485.

was facilitated by desorption of weakly bonded OM and disaggregation of mineral-organo composites (Mikutta et al., 2014). Spectroscopic and surface complexation analyses suggest that As is largely adsorbed by forming inner-sphere complexes on Fe (hydr)oxide-HS composites. There is ample evidence of enhanced adsorption of heavy metals on HS adsorbed phyllosilicates.

Climate change

Climate change and soil warming can accelerate microbial SOM decomposition rates causing increasing CO_2 concentration in the atmosphere. A meager reduction in soil C stocks is likely to have a drastic impact on the global C cycle and climate change. Approximately one third of the world's soil C stock exist in permafrost soils of the Arctic, which are perhaps most vulnerable to the projected global warming (Schuur et al., 2015). There are contrasting observations about the effects of increasing temperature and CO_2 concentration in the atmosphere on Arctic soil C, with modelling showing increased C sequestration (McGuire et al., 2018) and accelerated decomposition of SOM (Commans et al., 2017). These contradictory modelling results highlight knowledge gaps on the effects of climate change on a highly significant pool of the global soil C stock. In these models many important aspects are

not considered, for example, the transition from unprotected to mineral-protected soil C pools under warming, the effects of root exudates on MAOM, and the role of Fe and Al oxides in stabilizing SOM in deeper soils. Also, changed soil environmental conditions, particularly soil thermal and hydraulic changes, will disrupt the primary mechanism (freezing) for SOM persistence in the Arctic region. It remains uncertain how under changed conditions MAOM may attenuate the extent and rate of permafrost SOM decomposition following thaw.

Some earlier studies in soils from regions other than Arctic have suggested that the rise in CO₂ will lead to increases in plant biomass, and hence terrestrial C storage. However, these are an oversimplification, since belowground C storage dominates in some terrestrial ecosystems. Elevated CO₂ concentration in the atmosphere can cause complex effects on OM, including interacting belowground responses. The indirect effects of elevated CO₂ on the plant community, such as changes in quantity and quality of plant litter inputs and root exudation determine SOM responses, and these processes could affect POM and MAOM differently. Drake et al. (2011) showed that under elevated CO₂ enhanced rates of net primary production (NPP) in a forest ecosystem were sustained by a C-cascade through the root-microbe-soil system. The flux of C belowground increased under elevated CO₂ stimulated microbial activity, which accelerated the rate of SOM decomposition and stimulated tree uptake of N bound to this SOM. This process propelled and maintained greater C gain under elevated CO₂ because of increases in canopy N content and greater photosynthetic N-use efficiency. Increased root exudation under elevated CO₂ may increase the mineralization of native SOM or cause destabilization of MAOM (Phillips et al., 2010), thus may prevent soil C accumulation. More research is needed to get a clear understanding of the effects of elevated CO₂ on SOM accumulation under different land use systems.

Since a significant portion of the SOC is present in the MAOM fraction, a clear understating of the expected temperature increase on the stability of C in this fraction is required. Also, SOC sequestration via MAOM is a potential pathway to mitigate the effects of increased soil temperature and to reduce CO₂ emissions from soils. Lavallee et al. (2019) argued that targeted investigations on the direct effects of warming on the persistence and formation of POM and MAOM are needed to elucidate specific mechanisms of change. Such studies should be conducted in intact ecosystems so as to quantify the additive direct and indirect effects of warming on POM and MAOM and ultimately predict future SOM stocks with climate change.

Conclusions and the future

Organic C associated with soil minerals is relatively stable, and controls the long-term sequestration of SOM. The emerging view is that OM in MAOM largely consists of microbial residues and dead microbial cells or necromass, which are adsorbed on to minerals. In addition to chemical interactions, OM can be trapped into soil aggregates, which hinders access to soil microbes and thus remain protected. The type of adsorption mechanism involved and associated strength to protect the OM from microbial decomposition are governed by several factors including the type and properties of minerals present in the soil, the quantity and quality of OM, microbial decomposition products and soil environmental conditions.

Organo-mineral association in the soil is an important biogeochemical process that exerts influence on soil ecosystem services, such as, the cycling and preservation of soil nutrients, soil structure, and mobility and bioavailability of heavy metals. The preservation of OC in MAOM is acknowledged as a potential pathway to reduce CO₂ emissions and control global C cycle. However, the stability of C in MAOM in different soil types, land use and climatic conditions is not clear and current models provide conflicting results for projected global warming and climate change. Therefore, insights into mineral-OM interactions at molecular scale and stability of MAOM to microbial mineralization are crucial to manage the SOM and regulate the CO₂ emission from the soil. Modern techniques, such as nanoSIMS, STXM and NEXAFS, along with traditional techniques are being used investigate the key questions in relation to the stability and formation of MAOM. Often, physically fractionated pools are used to determine the spatial arrangement of primary and secondary MAOM; and chemically fractionated pools to elucidate molecular scale interactions of OM-mineral. The combined fractionation (physical + chemical) procedures are more effective than a single method and facilitate both spatial and molecular information. However, there is a lack of consistent approach in the fractionation procedures and subsequent characterization which is an hinderance to obtain consistent data for a range of soil systems. Most studies have been focused on mineral-OM-microbial interactions in surface soils, however, a significant portion of OM occurs in deeper soil horizons that needs more attention. Many investigations of the stability of OM associated with minerals have been laboratory based. It is important to evaluate mineral-OM-microbial interactions and the stability of C in MAOM in the rhizosphere of living plants. Such research may provide further insights into microbial contribution to organo-mineral association.

Abstract

Soil is a major global terrestrial ecosystem that offers the greatest variability of environments for the organisms populating it, ensuring the Earth's greatest biodiversity. Focusing on micro-environmental conditions, this chapter examines the importance of soil solid phase and pore structure on water and gas availability to soil organisms, along with importance of soil pH and other chemical characteristics. The vicinity and surfaces of pores is where most of soil microorganisms and micro- meso-fauna live, thus, properties and habitat value of different pore classes, as well as rhizosphere and detritusphere, the two soil hotspots of biological activity, are separately discussed.

Key points

- Soil offers the most diverse range of habitats among terrestrial ecosystems.
- Solid phase provides building blocks of the soil matrix, largely defining all other physical habitat characteristics.
- Distributions of water, O₂, pH, and organic matter within the soil matrix are the highly spatially and temporally variable drivers of soil biodiversity.
- Porosphere is where most soil organisms live and its special water and gas holding and transporting characteristics drive the life strategies of soil biota.
- Rhizosphere and detritusphere are two special "hotspot" habitats substantially differing in their environmental conditions from the bulk soil matrix.

Introduction

Habitat can be loosely defined as a space with a certain assemblage of biotic and abiotic characteristics enabling organisms to sustain themselves. Soil is one of the major global terrestrial habitats, hosting the greatest diversity of living organisms. As a layer of interaction between the Earth's crust, biosphere, and atmosphere, soil is uniquely different from any other habitat on Earth (Voroney, 2007).

Specific properties of soil habitats develop during soil formation, a process driven by five key factors: parent materials, climate, living organisms, topography, and time. Some of the characteristics of present-day soils that define their habitat features took hundreds to thousands of years to form, e.g., soil texture, mineralogy, and their vertical distribution down the soil profile. However, characteristics, such as soil organic matter content and soil structure can change much more rapidly, and thus, are greatly susceptible to the impact of what can be viewed as the sixth factor of soil formation – the anthropogenic influence.

When considering the soil as a habitat, it is important to keep in mind the vast diversity of soil inhabitants in terms of their size, life strategy, place in the food web, and ecosystem role. Soil organisms can range in body width from 1 to 2 µm for most bacteria,

10–100 μm for microfauna, 100–2000 μm mesofauna, and $>2000 \mu\text{m}$ for macrofauna. Soil megafauna is represented by vertebrates and large invertebrate organisms $>1 \text{ cm}$ in body length; however, some, such as the giant earthworm *Megascolides australis*, can grow to 1–3 m in length.

Soil as a habitat is perceived differently by the various groups of soil biota: for large borrowing animals, for small borrowing animals (earthworms), and for non-architectural soil meso- and micro-biota. The former two groups build their living space within the soil. The latter group are the organisms that rely on the existing physical framework of the soil space, which they populate but are not able to modify through direct physical actions. Of course, all organisms, especially the two latter groups, have a very substantial indirect effect on the soil formation and are continuously modifying many characteristics of soil habitats.

Soil microorganisms are among the most diverse soil inhabitants. They include all possible variants of food procurement: photoautotrophs, chemoautotrophs, and heterotrophs of all kinds. Remarkably diverse in environmental preferences, soil microorganisms can live in aerobic or anaerobic, wet or dry, cold or warm conditions; and include an equally remarkable abundance of facultative organisms with high versatility in their environmental preferences. This vast diversity has formed in response to a very wide range of conditions offered by the soil's living space to its inhabitants, and persistent soil heterogeneity continues to support this diversity. The biotic and abiotic conditions and resources that a soil environment can provide to one group of organisms might be completely different from what is available to another, even when the two are separated by just a few centimeters of physical space.

The following sections provide only a very general outline of the key characteristics to be considered when looking at what soil can potentially offer a particular organism. The primary focus is on the aspects of soil habitats that might be of key importance to microorganisms and micro- and mesofauna, only briefly touching on selected items of relevance to macrofauna and excluding the vertebrates all together. Habitat requirements of the vertebrates differ too much from those of the small soil dwellers to be discussed in sufficient detail in this article; they deserve a distinct article of their own!

Abiotic conditions

Solid phase

The soil solid phase plays a major role in determining properties and functions of soil habitats. This is what provides the physical scaffolding and building blocks of the soil matrix, largely defining all other physical characteristics. Yet, it is also the driver of soil chemical characteristics and the source of nutrients for plants and for many of the soil organisms. The solid phase consists of mineral grains of varying sizes interlaced with non-particulate soil organic matter (SOM) and mixed with particulate organic matter (POM), i.e., sizeable ($>0.053 \text{ mm}$) fragments of organic residues at various stages of decomposition (Fig. 1A).

The basic physical characteristic of the mineral portion of the solid phase of a soil is its particle size distribution, also known as its texture. Soil texture is commonly viewed as a composition of three particle-size categories: clay, silt, and sand. Proportions of these three key constituents, and especially, their spatial arrangement, define the structure of the soil's pore space, including pore size and shape distributions, pore connectivity, and tortuosity. They also largely determine the size and properties of soil surfaces. Pore volume and pore surface area form the dwelling spaces for most of the soil organisms and constitute a fundamental basis for the soil habitat.

The solid phase is an outcome of weathering of primary rocks, and the clay fraction is the common intermediate outcome of such weathering. Among the three particle-size categories, the surface area of clay particles is the largest due to its plate structure and spans from 20 to 40 $\text{m}^2 \text{ g}^{-1}$ in kaolinite to 500–800 $\text{m}^2 \text{ g}^{-1}$ in smectite. For comparison, the surface area in coarse sands is less than 0.1 $\text{m}^2 \text{ g}^{-1}$. The importance of clays is not just in their large surface areas: clay surfaces are also typically negatively charged, attracting and holding organic compounds, metal oxides and hydroxides, cations, extracellular enzymes of plants and microorganisms, and serving as the places of attachment for microorganisms themselves. Sizable surface areas of the soil solid phase, being largely the outcome of clay content, stimulate growth of microbial populations. Clays are often found to be associated with extracellular polymeric substances together forming particularly favorable environments for archaea and bacteria (Fig. 1B).

Soil solids are not just a physical environment but a source of nutrients for many organisms. Some organisms rely on procurement of specific nutrients from surfaces of soil minerals while others utilize SOM and POM. The attractiveness of the surfaces of soil particles as a habitat may vary for different organisms depending on their nutrient needs. For example, since NH_4^+ is often strongly absorbed by soil surfaces, ammonium oxidizing organisms tend to live in stronger contact with the surfaces compared to most of the heterotrophic bacteria.

As a contributor to soil habitat, SOM plays a unique and multifaceted role. It is the key gluing agent causing formation of soil structure, driving properties and connectivity of soil pores. At the same time, SOM decomposition is the main source of energy for soil microbes, as well as food for micro- and mesofauna organisms. Variability of SOM content at large spatial scales, such as across agricultural fields, is typically relatively modest; thus, it is often not sufficiently appreciated that SOM variability can be enormous at scales of few microns to few millimeters within the soil matrix. Indeed, SOM concentrations might vary from 2 to 10% in soils across a temperate forest watershed, yet, across a 1 mm distance within the soil matrix of any single spot within that watershed, SOM can span from a virtual zero to 100%. Thus, of two 1–2 μm sized bacteria separated by a 1 mm distance within the soil matrix, one might be enjoying an unlimited carbon and nutrient supply, while the other is living in an extremely inhospitable and resource poor

environment without any means to move to a better place. It is that microscale variability, together with a number of other sources of soil micro-heterogeneity, what results in an enormous diversity of soil microorganisms.

Light and temperature

Availability of light affects only the organisms living on the soil surface, in the top couple of millimeters of the profile, or in occasional wide cracks. It is of only minor relevance for soils of most ecosystems, with soil crusts of arid regions being one notable exception.

Temperature is as crucial a component in defining soil habitats as it is for any other terrestrial ecosystem, yet its importance is modulated by soil characteristics. The buffering of temperature fluctuations within the soil is greatly enhanced under wet conditions due to the large specific heat of water. Thus, spatial patterns in variability of soil temperature across landscapes typically follow the spatial distributions of soil water, with higher temperatures being associated with the soils of dry upslope locations and colder soils in wet depressions.

Only in the top few centimeters of the soil profile are organisms directly exposed to the atmospheric temperature fluctuations and, at times, the temperatures here can be more extreme than those in the air immediately above. Owing to the small heat conductivity of soil, at greater depths the temperature is less temporally variable and is more moderate than daily and seasonal aboveground extremes. The deeper within the soil profile the less variable are the temperatures, and the more insulated are the inhabitants from rapid temperature changes, including rapid freezing events. Reduction in temperature variability with depth is counted on in the life strategies of many soil mesofauna and microorganisms. Yet for many organisms inhabiting the top 5–10 cm of the soil profile, e.g., nematodes and microarthropods, aboveground factors mediating temperature fluctuations in the topsoil can

be of major importance. For example, the type of vegetation cover, such as a shady forest vs. an open pasture, can substantially influence warm season soil temperatures, while snow cover can restrict cold season temperature drops.

Water

The availability of rainfall water to soil biota is greatly affected by a multitude of topographical, vegetative, and edaphic factors. Only a portion of precipitated water infiltrates into the soil. The exact quantities are a function of a number of relatively stable environmental characteristics, including topography, vegetation, and soil properties, as well as some highly spatially and temporally variable features, e.g., antecedent soil water content and characteristics of individual precipitation events. Depending on rainfall characteristics, soils of runoff-prone areas in topographical depressions can receive an order of magnitude or more of the fallen precipitation as compared with hillslopes. The outcome is a substantial spatial variability in soil moisture distribution across topographically diverse landscapes with far-reaching effects on soil inhabitants. It drives spatial patterns in surface soil temperatures, redistribution of nutrients carried with surface and subsurface flow (such as NO_3^-), and of soil physical characteristics due to transport of soil particles, SOM, and POM with surface runoff.

The water that does infiltrate into the soil is subject to a multitude of influences that further enhance variability in its spatial distribution and role in soil habitat formation (Fig. 2). First, the incoming water rarely travels through the soil profile as a uniform front, instead, a large portion of it quickly moves through via large pores or established flow paths in a phenomenon called preferential flow (primary paths, Fig. 2). In some instances, as much as 90% of the incoming water can be directly transported into the subsoil by preferential flow paths, leaving the bulk of the topsoil relatively dry. The distribution of the water that does enter the soil matrix is also highly heterogeneous. In relatively dry finer-textured soils the water is quickly absorbed into the fine pores of the matrix (tertiary paths, Fig. 2), leaving large pores empty. In wet conditions water flow takes place through non-preferential paths of both large and small pores of the soil matrix. Besides the influence of antecedent water content, the rates and volumes of water fluxes are driven by soil texture and structure, while the magnitude of the preferential flow into deeper soil horizons is also affected by the quantity and intensity of surface water supply via precipitation and runoff.

Water flow pathways play an important role in dispersion of microfauna and microorganisms through the soil and affects their spread to new regions within the soil profile vertically, as well as laterally. The rate of water flow through the soil matrix under unsaturated conditions is significantly (orders of magnitude) slower than the saturated one. The unsaturated flow is driven mostly by capillary forces when water moves along the gradients of matric potential. While slow and short-distanced as compared to the saturated flow, it provides yet another important mode of transport and means for dispersal for bacteria, viruses, and similarly sized organisms. They can be absorbed and tightly held on the air-water interfaces, that are ubiquitous in unsaturated soil, and be carried along as the capillary flow moves such interfaces across the soil matrix (Mills, 2003). Their own motility can take such organisms only over very short distances and even then only when the right water conditions, such as large, deep, connected water menisci, are present.

Fig. 2 A conceptual model of the three types of water flow paths within the soil matrix highlighting their contributions to flow and transport processes (Franklin et al., 2021). From Franklin SM, Kravchenko AN, Vargas R, Vasilas B, Fuhrmann JJ, and Jin Y (2021) The unexplored role of preferential flow in soil carbon dynamics. *Soil Biology & Biochemistry* 161.

In soils of humid regions, wet conditions prevail and the soils are often at either fully saturation or at field capacity, i.e., a state when gravimetric forces drained the largest of pores. There the large pores are filled as well, yet in a very uneven manner, with menisci and partially filled spaces. Recently, with advances in X-ray and neutron computed micro-tomography imaging, the magnitude of micro-scale variability in water distribution within the soil matrix started to be fully appreciated. Air-pockets within apparently fully-saturated soil, as well as water-pockets within large pores of an unsaturated soil, might be a rule rather than an exception, as opposed to an expectation of relatively evenly distributed water menisci within the soil matrix in a manner consistent with capillary theory. High variability in water distribution suggests that even when soil becomes unsaturated the water bodies sufficiently large to support movement in water might persist for some periods of time. On the other hand, soils of dry and temperate regions are below field capacity either year-round or most of the time during the warm season. In such settings there will be hardly any water menisci or other connected water bodies big enough to sustain motility of microorganisms. Thus, only the pore surface provides the lasting stable environment in the form of water films or menisci of varying thickness, where microorganisms can live on for lengthy periods of time, allowing species persistence and reproduction. Sedentary existence of microorganisms attached to the surfaces of pores is likely the rule. Together with high variability at small-scale for resources and environmental conditions, it leads to the exceptionally high diversity of soil microorganisms, with a seemingly contradictory observations of diversity as high within a few-cm of soil as within a few-km watershed.

For many organisms the challenge might not be how to survive the short-term full immersion, but how to quickly switch from sedentary living on the air-solid or water-solid interfaces to benefitting from planktonic lifestyle and or slow movement on thin water films. It is also a question of how to survive onsets of dryness. Impressive diversity of motility mechanisms and flexibility of their use in soil bacteria as well as production of extracellular polymeric substances to stay hydrated are examples of adaptations to high temporal and spatial heterogeneity in water distribution.
